## ACKNOWLEDGMENTS

This research was supported by the National Oceanic and Atmospheric Administration, Office of Global Programs (NOAA-OGP), Award No. NA96GP0451, with the able assistance of Bill Murray, Caitlin Simpson, and Rick Lawford. Additional support was provided by the U.S. Weather Research Program. The authors are particularly grateful for the assistance of Frank Richards and Joanna Dionne of the National Weather Service (NWS) Hydrologic Information Center and other NWS staff including Paul Polger and John Ogren (Silver Spring, MD) and Robert Glancy and Frank Cooper (Denver, CO).

Valuable assistance and comments were received from David Wingerd, U.S. Army Corps of Engineers; Stan Changnon and Ken Kunkel, Illinois State Water Survey; Bill Cappuccio, National Flood Insurance Program (Iowa); Lisa Flax, National Ocean Service; Jacki Monday, Natural Hazards Research and Applications Information Center; Kathleen Miller, National Center for Atmospheric Research; and Tom Grazulis, The Tornado Project.

Many state emergency management agencies provided information for this study. We are especially grateful to Michael Sabbaghian, California Governor's Office of Emergency Services, for providing data and assistance related to the California 1998 El Niño disaster. Information was also provided by:

Lee Helms, Alabama Emergency Management Agency
Karma Hackney, Dana Owens, and Tom Mullins, California Governor's Office of Emergency Services
Larry Lang, Colorado Water Conservation Board
Yusuf Mustafa, Florida Division of Emergency Management
Shirley Collins, Florida Bureau of Recovery and Mitigation, Dept. of Community Affairs
Gary McConnell, Georgia Emergency Management Agency
Edward Teixeira, Hawaii State Department of Defense
Robert Sherman, Illinois Emergency Management Agency
Phil Roberts, Indiana State Emergency Management Agency
David Eash, Iowa Dept. of Natural Resources
Art Jones, Louisiana Office of Emergency Preparedness
Stephen J. McGrail, Massachusetts Emergency Management Agency
Doran Duckworth, Michigan Dept. of State Police, Emergency Management Division
Sherrill Neudahl, Minnesota Dept. of Public Safety, Division of Emergency Management
Glenn Schafer and Stuart Shelstad, Minnesota Farm Service Agency
Chuck May, Missouri State Emergency Management Agency
Kay Phillips, Ohio Emergency Management Agency, Response and Recovery Branch
Dennis Sigrist, Oregon Emergency Management Agency
John Knight, South Carolina Emergency Preparedness Division
Joan Peschke, Texas Emergency Management, Recovery Section
Michael Cline and Harry Colestock, Virginia Dept. of Emergency Services

Chuck Hagerhjelm and Terry Simmonds, Washington State Military Dept., Emergency Management Division
John Pack, West Virginia Dept. of Military Affairs and Public Safety, Emergency Services
Robert J. Bezek, Wyoming Emergency Management Agency
Much assistance was provided by librarians at the National Center for Atmospheric Research and the National Oceanic and Atmospheric Administration in Boulder, CO, and the staff of the U.S. Army Corps of Engineers library at Fort Belvoir, VA.

Finally, special thanks to Jennifer Oxelson for constructing the website, to Roberta Klein for helpful comments on the manuscript, and to D. Jan Stewart, Anne Oman, and Jan Hopper for preparing the report for publication.

## EXECUTIVE SUMMARY

Flood damage continues to increase in the United States, despite extensive flood management efforts. To address the problem of increasing damage, accurate data are needed on costs and vulnerability associated with flooding. Unfortunately, the available records of historical flood damage do not provide the detailed information needed for policy evaluation, scientific analysis, and disaster mitigation planning.

This study is a reanalysis of flood damage estimates collected by the National Weather Service (NWS) between 1925 and 2000. The NWS is the only organization that has maintained a long-term record of flood damage throughout the U.S. The NWS data are estimates of direct physical damage due to flooding that results from rainfall or snowmelt. They are obtained from diverse sources, compiled soon after each flood event, and not verified by comparison with actual expenditures. Therefore, a primary objective of the study was to examine the scope, accuracy, and consistency of the NWS damage estimates to improve the data sets and offer recommendations on how they can be appropriately used and interpreted.

This report presents the following three data sets, which are also available on the World Wide Web at www.flooddamagedata.org:

- Estimated flood damage in the U.S. (1926-1979 and 1983-2000, by fiscal year;
- Estimated flood damage for each state in the U.S. (1955-1979, by calendar year, and 1983-2000, by fiscal year); and
- Estimated flood damage, by river basin, for the U.S. (1933-1975, by calendar year).

We found that the NWS collection and processing of flood damage data were reasonably consistent from 1934 to the present, except during the period 1976-1982. Data from NWS files and other sources made it possible to reconstruct state and national flood damage estimates for 1976-1979. However, little data was collected during 1980-1982 and large errors were discovered in estimates developed later for that period. As a result, the years 1980-1982 are excluded from the reanalyzed data sets.

Evaluation of the accuracy of the estimates led to the following conclusions:

1. Individual damage estimates for small floods or for local jurisdictions within a larger flood area tend to be extremely inaccurate. When damage in a state is estimated to be less than $\$ 50$ million (in 1995 dollars), estimates from NWS and other sources frequently disagree by more than a factor of two.
2. Damage estimates become more accurate at higher levels of aggregation. When damage in a state is estimated to be greater than $\$ 500$ million, disagreement between estimates from NWS and other sources are relatively small ( $40 \%$ or less). The relatively close agreement between NWS and state estimates in years with major damage is reassuring, since the most costly floods are of greatest concern and make up a large proportion of total flood damage.
3. Floods causing moderate damage are occasionally omitted, or their damage greatly underestimated, in the NWS data sets. Missing NWS estimates were discovered for floods in which the state claimed as much as $\$ 50$ million damage.

In summary, the NWS flood damage estimates do not represent an accurate accounting of actual costs, nor do they include all of the losses that might be attributable to flooding. Rather, they are rough estimates of direct physical damage to property, crops, and public infrastructure. Estimates for individual flood events are often quite inaccurate, but when estimates from many events are added together the errors become proportionately smaller.

At the national level, these findings suggest that annual damage totals are reasonably accurate because they are sums of damage estimates from many flood events. State annual damage estimates are more problematic. Both frequency and magnitude of damage must be considered, because damaging floods do not occur every year in most states. Flood frequency cannot be determined simply by the presence or absence of a damage estimate because reporting, particularly for small floods, is unreliable.

Aggregation is a key to reducing estimation errors. To compare flood damages between states, aggregate the damage estimates over many years and compare the sums. To compare damage between years, aggregate yearly state damage estimates over multi-state regions. Even when the estimates are highly aggregated, be aware that a substantial amount of variability is caused by estimation errors and interpret the results accordingly.

When properly used, the reanalyzed NWS damage estimates can be a valuable tool to aid researchers and decision makers in understanding the changing character of damaging floods in the United States. Users of the reanalyzed data are advised to take the following precautions:

- To compare flood damage over time, adjust for changes in population, wealth, or development.
- To compare damage in different geographical areas, control for differences in population and in the incidence of extreme weather events during the period of study.
- Use damage estimates for individual floods with caution, recognizing that estimation errors are large. Comparison of individual floods might be better done using nominal or ordinal damage levels. Look for qualitative descriptions to compare the nature and impacts of the damage.
- Different agencies define "flood" and "flood damage" somewhat differently. Check for incompatibilities between data from different sources before seeking to combine sources or aggregate data.

The NWS damage estimates are not reliable enough to be a basis for critical decisions, such as setting flood insurance premiums or evaluating the cost-effectiveness of specific hazard mitigation measures. Better damage data are needed to evaluate the effectiveness of specific mitigation measures designed to reduce flood losses.

## 1. INTRODUCTION

## A. Why We Need Historical Flood Damage Data

The National Weather Service (NWS) estimates that flooding caused approximately \$50 billion damage in the U.S. in the 1990s (NWS-HIC 2001). Although flood damage fluctuates greatly from year to year, estimates indicate that there has been an increasing trend over the past century (Pielke and Downton 2000). Some have speculated that the trend is indicative of a change in climate (e.g., Hamburger 1997), some blame population growth and development (e.g, Kerwin and Verrengia 1997), others place the blame on federal policies (e.g., Coyle 1993), and still others suggest that the trend distracts from the larger success of the nation's flood policies (e.g, Labaton 1993).

To understand increasing damage and assess implications for policy, decision makers need to resolve the independent and interdependent influences of climate, population growth and development, and policy on trends in damage. Increased flood damage due to changing climate requires different policy actions than would damage increases due to implementation of flood policies.

The available records of historical flood damage are inadequate for policy evaluation, scientific analysis, and disaster mitigation planning. There are no uniform guidelines for estimating flood losses, and there is no central clearinghouse to collect, evaluate, and report flood damage. The data that exist are rough approximations, compiled by the NWS from damage estimates that are reported in many different ways. Moreover, most published summaries of the damage estimates focus primarily on aggregate national damage totals.

Scientists need historical flood damage data at a variety of spatial scales to analyze variations in flood damage and what contributes to them. For example, during El Niño years, southern California receives more precipitation than in the typical year. Conventional wisdom suggests that the increase in precipitation should result in an increase in damaging floods. If California's emergency planners knew this to be the case, they could prepare for the floods that come with El Niño, possibly reducing damage. In this case, scientists looking for a causal relationship would want to determine to what degree historical high damage years in southern California are associated with El Niño events. This requires sub-state-level data sets, rather than a national data set.

Social scientists looking at the effect of policies designed to reduce flood damage also need access to historical data at regional and local scales. Take the example of the National Flood Insurance Program, created in 1968 to "assist in reducing damage caused by floods" (42 U.S.C. § 4102 (c)(3)). Researchers evaluating the program would like to isolate the effect of the program from all other factors influencing flood damage in particular areas. At the river basin or community level, the effect of a federal policy implemented in 1968 might be isolated and measured.

In sum, historical damage data are essential for any study that seeks to understand the role that climate, population growth and development, and policy play in determining trends in flood damage. Some studies might require data at the national level, and others at the state or
local level. Moreover, researchers need guidance to use the data effectively. Some data sets are not accurate enough for certain types of analysis.

## B. Sources of Historical Flood Damage Data

Ideally, a national database of historical flood damage should cover the entire country over a long time period, using consistent criteria and methods in all times and places. Table 1-1 compares possible sources of damage data. The National Weather Service is the only organization that has maintained a long-term and fairly comprehensive record of flood damage throughout the U.S. Insurance company records include only insured property. Records of the Federal Emergency Management Agency (FEMA) include only property that qualifies for federal assistance in presidentially declared disasters. Few state and local governments maintain damage records beyond those required by FEMA. Only in newspaper archives from cities and towns across the nation might one find more complete reporting of historical flood damage. Indeed, a newspaper archive could be the best source of information on flood damage in a particular locale. But the parochial nature of such data makes aggregation problematic.

For long-term coverage of the entire nation, and of most states, the NWS data sets appear to be the best available source of flood damage estimates. However, the scope, accuracy and consistency of the data must be evaluated to determine how they can be appropriately used and interpreted.

## C. Scope of the NWS Flood Damage Data

The NWS Hydrologic Information Center (NWS-HIC 2001) describes the data as "loss estimates for significant flooding events," providing estimates of "direct damages due to flooding that results from rainfall and/or snowmelt." However, key concepts such as "flood" and "flood loss" are defined differently by various agencies and researchers depending on their objectives. Appropriate use of NWS damage data requires understanding of what is and is not included.

## Types of Flooding

Ward (1990) defines a flood broadly as "a body of water which rises to overflow land which is not normally submerged." This definition covers river and coastal flooding, rainwater flooding on level surfaces and low-gradient slopes, flooding in shallow depressions which is caused by water-table rise, and flooding caused by the backing-up or overflow of artificial drainage systems.

The NWS includes damage from most types of flooding listed above, but excludes ocean floods caused by severe wind (storm surge) or tectonic activity (tsunami). These are excluded because, although they result in water inundation, they are not hydrometeorological events. In addition, the NWS excludes damage that results from mudslides because, though they are caused by excess precipitation, they are considered primarily a geologic hazard.

Table 1-1. Sources of flood damage estimates.

| Source | Timespan | Spatial Scale | Scope |
| :--- | :--- | :--- | :--- |
| National Weather Service flood <br> damage data sets | 1925-present | Nation <br> State <br> Basin | Estimates of direct physical damage from <br> significant flooding events that result <br> from rainfall or snowmelt |
| Insurance records <br> (National Flood Insurance <br> Program, private insurers) | 1969-present | Nation <br> Community | Personal property claims made by <br> individuals holding flood insurance |
| Disaster assistance records <br> (Federal Emergency <br> Management Agency) | 1992-present | Nation <br> State | Federal and state outlays for public <br> assistance, individual assistance, and <br> temporary housing in presidentially <br> declared disasters |
| State and local government <br> records | Varies | State | Varies |
| Newspaper archives | Varies | Community | Varies |

## Definition of Loss, Damage, and Damage Estimates

Researchers specializing in natural hazards have expressed a need for more complete documentation of losses, including both direct and indirect costs associated with flooding (Mileti 1999; National Research Council 1999; Heinz Center 2000). Direct costs are closely connected to a flood event and the resulting physical damage. In addition to immediate losses and repair costs they include short-term costs stemming directly from the flood event, such as flood fighting, temporary housing, and administrative assistance. By contrast, indirect costs are incurred in an extended time period following a flood. They include loss of business and personal income (including permanent loss of employment), reduction in property values, increased insurance costs, loss of tax revenue, psychological trauma, and disturbance to ecosystems. They tend to be more difficult to account for than direct costs (Heinz Center 2000).

The NWS describes its flood loss data as estimates of "direct damages" including, for example, loss of property and crops and costs of repairing damaged buildings, roads, and bridges. The NWS estimates have usually been restricted to direct physical damage, a subset of the losses generally considered to be direct costs.

The dollar figures in the NWS damage data are estimates compiled soon after each flood event, before the actual costs of repair and replacement can be known. They are not verified by comparison with actual expenditures. The estimates are gathered from diverse sources, some who use accurate estimation methods (e.g. insurance companies) and others who do not (e.g. newspapers). Therefore, NWS damage data are best described, not as "loss data", but as "damage estimates."

## D. Purpose and Methods

Objectives of this study are (1) to assemble a national database of historical flood damage based on NWS damage estimates, making it as complete and consistent as possible; (2) to describe what the estimates represent; (3) to evaluate the accuracy and consistency of the estimates; and (4) to develop guidelines for use of the data and make it widely available to users. Steps followed to achieve these objectives are described below.

## 1. Compilation of historical flood damage data sets.

The NWS Hydrologic Information Center (NWS-HIC) is responsible for compiling and archiving flood damage estimates collected from NWS field offices throughout the U.S. Its staff members provided several data sets and access to files and publications archived in their office at Silver Spring, Maryland. This report augments published NWS data with information from NWS files and reports of other federal and state agencies. The following data sets are presented:
a. Estimated flood damage in the United States (1926-1979 and 1983-2000, by fiscal year);
b. Estimated flood damage for each state in the U.S. (1955-1979, by calendar year, and 19832000, by fiscal year); and
c. Estimated flood damage, by river basin and drainage, for the U.S. (1933-1975, by calendar year).

## 2. Review of data collection and reporting methods used by the NWS.

In interviews, staff of NWS-HIC and two NWS field offices described their data and recent data collection procedures. NWS-HIC documents and several editions of the NWS Operations Manual provided additional information on past and present procedures. This report describes the nature of the damage estimates and provides a guide to their interpretation and use.

## 3. Evaluation of accuracy and consistency of the damage estimates.

This report critically examines criteria and methods used by the NWS in collecting past and present damage estimates to identify likely sources of inaccuracy. To understand the inaccuracy generally inherent in damage estimation, the report uses statistical comparison methods to assess a California data set containing both preliminary damage estimates and actual cost information. Then it uses similar statistical methods to compare NWS damage estimates with independent estimates from state sources to evaluate the variability in flood damage estimates. Finally, it assesses the impacts of errors and omissions on aggregated damage estimates.

## 4. Development of guidelines for use of the data.

Evaluation results show substantial errors in many of the damage estimates. Uncertainty about the accuracy of the estimates implies that comparisons of flood damage estimates from different flood events or different locations must be undertaken with caution. The report presents examples that illustrate appropriate and inappropriate ways of using the damage data and suggests ways of reducing the impact of errors.

The data and an associated Users Guide are available on the World Wide Web, at www.flooddamagedata.org.

## E. Organization

This report is organized as follows. Section 2 describes NWS procedures for obtaining damage estimates and other sources used in compiling the reanalyzed data sets. Section 3 presents the reanalyzed data sets and explains how they were developed. Section 4 describes the types of inaccuracy users should expect in the damage estimates. Section 5 compares damage estimates from different sources and analyzes the accuracy of the estimates. Section 6 suggests ways of dealing with data omissions and inconsistencies. Section 7 provides guidance for use and interpretation of the reanalyzed data, with examples and warnings, and concludes with recommendations regarding future collection and dissemination of flood damage estimates.

## 2. SOURCES OF FLOOD DAMAGE ESTIMATES, 1926-2000

For nearly a century, the NWS and its predecessor, the U.S. Weather Bureau, have collected flood damage estimates through a nationwide system of field offices. The quality of the flood damage estimates is uneven, depending on operational constraints at particular field offices and diverse sources of damage reports. Policies and procedures for collecting and compiling the estimates have changed somewhat in the course of time.

## A. Overview of Historical NWS Estimates

The NWS has published flood damage estimates almost annually since 1933. From 1933 to 1975 , reporting units were defined by natural boundaries (river basins), which could be useful for local planning on issues such as water supply, agriculture, and flood control. In 1955, annual summaries of damage by state were added. Consistent administration, methodology, and format of the published reports suggest that these data form a reasonably homogeneous time series.

From 1976 through 1979, reduction of funding led to cutbacks in the compilation of flood damage data. Data collection was consistent with prior years, but there appears to have been less checking and updating of initial damage information. Publication of annual summaries ceased. In 1980, compilation of flood damage estimates was discontinued entirely.

In 1983, Congress ordered the U.S. Army Corps of Engineers (USACE) to provide annual reports of flood damage suffered in the U.S. The USACE contracted with the NWS to provide the required data. NWS estimates of flood damage in each state have been published annually since 1983 by the USACE. The NWS Hydrologic Information Center (NWS-HIC) has gradually improved its procedures for compiling and checking the damage estimates.

The long-term consistency in collection of flood damage data results from its connection to weather forecasting and storm warning operations of the NWS. Since at least 1950, reports on severe storms have been submitted regularly to NWS headquarters from field offices distributed across the U.S. The reports include descriptions of severe storms and associated deaths and damage. Since 1959, these reports have been published monthly in a NOAA periodical, Storm Data, and have provided the initial information used in compiling flood damage estimates. However, the field office reports are filed soon after the storm events and receive only minimal quality control before publication, thus the damage estimates provided are preliminary and incomplete. Staff at NWS headquarters perform considerable checking and follow-up to produce final flood damage estimates.

This brief overview highlights a major change in the purpose and format of the flood damage data. Before 1980, the NWS compiled damage estimates for meteorological and hydrological purposes, based on natural units such as watersheds. Annual estimates were compiled by calendar year. Since 1983, the USACE and NWS have prepared flood damage information for Congress, whose members focus on the state as a political unit. Estimates are compiled by federal fiscal year.

## B. Present Methods of Compiling Flood Damage Estimates

The staff of NWS-HIC willingly answered our questions about methods used in recent years to collect and compile damage estimates. However, none had direct experience with the methods used before 1989. They provided to us copies of their flood damage data sets and made available all of the materials in their historical archives, including publications of federal agencies, files containing flood reports submitted monthly by the NWS field offices, and notes made by former staff who compiled the data into annual reports.

The NWS operates approximately 120 field offices distributed across the U.S. and its territories. Each office provides weather and hydrological forecasts for an assigned area and issues warnings during severe weather and flood events. Most offices have a Warning Coordination Meteorologist (WCM) who issues storm and flood warnings in the forecast area. The WCM is also responsible for submitting monthly reports on severe storm events to the NWS, including deaths and estimates of damage to property and crops. The descriptions, deaths, and damage estimates are published monthly in Storm Data.

Compiling estimates of storm damage is a minor part of the job, receiving little attention from many WCMs (Frank Richards, NWS-HIC, personal communication, 2/16/00). Field offices differ greatly in the regularity and completeness of their damage reports. Their staff obtain damage estimates from numerous local sources, and cannot always know how those estimates were made and what is included.

A meteorologist at NWS-HIC is responsible for collecting flood damage reports from all of the field offices and checking the damage estimates. NWS-HIC staff are in a good position to track damaging floods because they receive the first flood and flash flood warnings issued by all of the field offices and produce the daily National Flood Summary (NWS-HIC website under Current Flooding). They also receive monthly summaries of significant hydrological events from the field offices. Hence the meteorologist is aware of most flooding events as they occur, receives narrative descriptions monthly, and can check whether estimates are received for all severe floods.

Floods that appear to involve less than $\$ 50,000$ in damage are entered into the database but generally not checked for accuracy or completeness. When it appears that damage could exceed $\$ 50,000$, and estimates are missing or seem unreasonable based on descriptions of weather and flood conditions, other reports (e.g. news accounts), and prior experience in compiling damage records, the meteorologist contacts the field office and asks for more information and better estimates. In practice, it is often difficult to clearly separate the estimates of damage to property and crops. Therefore, in recent years, NWS-HIC has combined the estimates of property and crop damage into a single damage estimate.

In most cases, damage information is collected within three months after the flood event. It is most difficult to get the information for large floods because attention in the field office is focused on other more urgent tasks related to the event.

Historically, field office personnel obtained their damage estimates primarily from newspapers (Paul Polger, NWS, pers. comm., 2/16/00). Today, however, they obtain estimates
through a variety of contacts in their area such as emergency managers, insurance agents, and local officials. Many offices also subscribe to a newspaper service, which allows the staff to search for any story having to do with weather.

Newspapers and emergency managers are the best sources of information, according to a WCM in Boulder, Colorado (Robert Glancy, NWS, pers. comm., 8/24/01). If a flood has received a presidential disaster declaration, information can be obtained from damage assessments by Federal Emergency Management Agency (FEMA) storm survey teams that travel to the flood scene. Estimates of damage to insured property can be obtained from local insurance agents. However, the estimation process is not performed with rigorous attention to accuracy. One WCM described using the following procedure: Since the largest insurer handles about $25 \%$ of the insured property in the local area, an estimate of insured losses is obtained by getting a cost estimate from that insurer and multiplying by four (John Ogren, NWS, pers. Comm., $8 / 29 / 01$ ). A full survey of each damaged structure does not take place; instead, in many cases a simplifying formula is used to estimate damage (John Ogren, pers. comm., 8/29/01).

Crop damage estimates are obtained from U.S. Department of Agriculture (USDA) agents or from monthly "flash" reports that are compiled from claims that farmers make to USDA. Damage is calculated based on expected return on the crop: Average yield is multiplied by the number of acres damaged, the estimated percentage of the crop lost, and the expected sale price based on the market at the time of event (John Ogren, NWS, pers. comm., 8/29/01). Unlike property damage, the estimates of crop damage rely on self-reporting by farmers and permit reports to be submitted up to 60 days after the event. After a major flood event market prices often rise so that, by the time of filing, the market price claimed may be higher than the market price at the time of the flood event.

Storm Data's compilers vary widely in terms of training and expertise (Frank Richards, pers. comm., 6/27/01). NWS provides operations manuals to its staff, which explain how to collect and report flood damage. However, one compiler reports that he received most of his training from previous employees who had experience with Storm Data compilation. He was referred to NWS manuals after he had been doing the job for some time (Frank Cooper, pers. comm. 8/27/01).

Instructions for estimating damage have changed in successive versions of the NWS Operations Manual. For example, the 1985 revised manual required that damage estimates be entered by checking off damage categories (though actual dollar amounts could be entered in the narrative section of a report), and specified that damage below $\$ 5,000$ could be omitted or entered as zero. Furthermore, the manual stated, "Damage resulting from flash floods and floods should be reported only if it is the result of local rainfall but not if it is the result of heavy rain upstream, i.e., that which fell more than 24 to 48 hours in advance of the flooding" (NWS 1985, chap. 42, p. 14). In other words, NWS wished to collect damage estimates only for floods that were the result of localized precipitation. It is uncertain how widely this rule was followed, but it was eliminated less than a decade later. In the 1994 revised manual, instructions simply state, "Damage resulting from flash floods and floods should be reported by each office in whose county area of forecast responsibility the damage was reported." The 1994 revision also eliminated the use of damage categories, specifying that damage estimates should be entered as
actual dollar amounts, rounded to three significant digits. The manual further advised, "Focus attention on providing reasonable estimates of larger events (damages greater than $\$ 100,000$ )" (NWS 1994, chap. 42, p. 10).

The field office procedures for collecting flood damage data have some notable strengths and weaknesses. Damage estimators trained by their predecessors are likely to maintain continuity in the data sets, because the training ensures that collection methodology does not change from employee to employee. However, since the NWS operations manual is not always used for guidance, employees may overlook changes in official NWS data collection policies.

## C. Sources of Historical NWS Estimates

The NWS and the U.S. Weather Bureau published flood reports regularly in five publications from 1918 through 2001. Table 2-1 summarizes the time periods covered and the information provided by each of these sources. In the early years, damage estimates were published only after major flood events. Annual reporting of flood damage throughout the U.S. commenced in 1933.

From 1934 to 1975, the River and Flood Service published monthly flood reports and annual summaries of flood damage by river basin, first in The Monthly Weather Review and later in Climatological Data National Summary. Two formats were consistently used for the annual summaries, one during 1934-1947, the other during 1948-1975. Annual damage estimates by state for calendar years 1955-1975, and monthly damage estimates for the nation during 19251975, were calculated and published in later reports (NWS 1975, 1977).

The 1978 annual summary issue of Climatological Data National Summary announced "Compilation of the General Summary of National Flood Events and Flood Damage Statistics has been delayed. These data will be published later." However publication of Climatological Data National Summary ceased the following year.

For several years after the demise of Climatological Data National Summary, the only published NWS records of flood damage were those included in Storm Data monthly reports. As noted above, these reports often were incomplete and received little checking. Until 1995, most damage estimates were indicated by marking a damage category. (Difficulties of using estimates based on the damage categories are discussed in Section 4.) Until the mid-1970s, the cause of damage was often listed as "heavy rain", rather than "flood", even when flood damage was mentioned in the description. Flood descriptions gradually became more detailed in the 1980s. In general, the flood descriptions provide ample information about precipitation and river flows, but only brief mention of damage.

Table 2-1. Published sources of flood damage estimates from the NWS and U.S. Weather Bureau (WB).

| Publication | Years of Flood Damage Included | Spatial Aggregation | Time Periods Summarized | Information Provided |
| :---: | :---: | :---: | :---: | :---: |
| Report of the <br> Chief of the <br> Weather <br> Bureau (WB) | $\begin{aligned} & 1918- \\ & 1933 \end{aligned}$ | River basin | Water year (Oct - Sep) | Describes large flood events. Occasionally gives flood damage estimates for individual large events. (First national flood damage total reported in 1934.) |
| Monthly <br> Weather <br> Review (WB, 1934-1949) | $\begin{aligned} & 1933- \\ & 1947 \end{aligned}$ | River basin | Calendar year | Annual summaries describe damage in major floods. <br> Tables give estimated damage for all major river drainages. |
| Climatological <br> Data, National <br> Summary <br> (WB, NOAA, 1950-1977) | $\begin{aligned} & 1948- \\ & 1977 \end{aligned}$ | River basin | Calendar year | Monthly summaries describe flood damage and deaths in "notable" flood events. <br> Annual summaries through 1975 give tables of damage in major river drainages. <br> General summaries for 1972 and 1975 also give damage by state for each calendar year since 1955 and national flood damage and deaths by month and year since 1925 . |
| Storm Data (WB, NOAA) | 1959 present | County or multi-county area | - | Monthly reports on storm events sometimes give brief descriptions of damage. Estimated damage to property and crops checked off on logarithmic scale until 1994, reported in thousands of dollars since 1995. |
| Annual Flood <br> Damage <br> Report to <br> Congress <br> (USACE) | 1983present | State | Federal fiscal year (Oct Sep) | Annual reports describe major flood events and provide table of flood damages suffered, by state. Recent reports give 10-year summary tables of flood damage and deaths, by state. |

In 1983, when Congress asked the USACE for annual reports of flood damage suffered, Storm Data was the only available nationwide source of damage estimates. Under contract to USACE to provide estimates, NWS-HIC compiled the limited information available. In the years that followed, methods of compiling and checking the estimates were established and gradually improved. These estimates are published annually in the U.S. Army Corps of Engineers Annual Flood Damage Report to Congress (USACE 1983-2001).

In the USACE damage reports from 1983 to 1988, narrative descriptions of floods are quite brief ( $1 / 2$ to $3 / 4$ page). Many states have no damage estimate but an asterisk $\left({ }^{*}\right)$ indicates that flooding occurred. The 1984 report explains that the table gives a summation of all major flood events but that damage estimates are unavailable for minor flood events. After 1988, the descriptions of flooding and flood damage are more detailed. Beginning in 1991, the asterisk is no longer used and there are few zero entries in the tables. It appears that considerably more record keeping and analysis has gone into damage reports since 1989.

Table 2-2 lists the types of flood loss reported in each of the above publications. From 1933 to 1977, estimates were divided into several categories, separated into property and agricultural damage, compiled by river basin, and presented by calendar year. In 1983, the loss categories, spatial scale, and time period changed. Estimates were summarized by state and fiscal year. In 1993, the distinction between property and agricultural damage was eliminated. Throughout the entire period, estimates focused on direct physical damage, though some data on loss of business and wages were included before 1947. Little is known about the methods used to compile and check the estimates prior to 1980. The published reports themselves show an intent to include all parts of the United States and all types of physical damage.

## D. Additional Sources of Flood Damage Estimates

To compile and evaluate a continuous time series of damage estimates, we supplemented the NWS estimates with comparable data from other sources. Comparable estimates should represent direct physical damage in significant flood events. Extensive information would be required to fill the 1976-1982 gap in the state and national estimates. In addition, independent estimates or cost information were needed to assess the accuracy of the estimates. Reports from many sources were used to confirm damage estimates and to provide information about specific floods.

## Reports by Federal Agencies and Task Forces

Several federal agencies prepare reports after severe flood events, in order to study the causes of particular floods and recommend improvements in systems of flood monitoring, warning, or control. Some of these reports include descriptions of earlier floods in the community, and some provide damage estimates.

Table 2-2. Types of flood loss reported during each era.

| Reporting Years | Publications | Types of Flood Loss Consistently Included |
| :---: | :---: | :---: |
| 1933-1946 | Monthly Weather Review | Tangible property totally or partially destroyed <br> Prospective crops <br> Matured crops <br> Livestock and other movable farm property <br> Suspension of business, including wages of employees |
| $\begin{aligned} & 1947 \\ & 1948-1977 \end{aligned}$ | Monthly Weather <br> Review <br> Climatological Data, <br> National Summary | Urban Property <br> Residential <br> Commercial <br> Public <br> Rural Property <br> Crops <br> Livestock <br> Other <br> Other Property <br> Railroads, bridges, highways, etc. <br> Public utilities <br> Miscellaneous <br> Unclassified |
| 1959-present | Storm Data | Property damage Crop damage |
| 1983-1992 1993-present | Annual Flood <br> Damage Report to Congress | Property damage <br> Agricultural losses $\qquad$ <br> Damages suffered |

Post-flood reports prepared by district offices of the U.S. Army Corps of Engineers (USACE) often provide fairly detailed damage estimates that are more complete than NWS estimates because they are compiled many months after the flood event. The Tennessee Valley Authority (TVA) publishes post-flood reports, similar to USACE reports, for areas of the southeastern U.S. under its jurisdiction. Post-flood reports from USGS, NOAA, and the U.S. Weather Bureau usually focus on hydrological and meteorological conditions preceding and during the flood event, with only brief mention of damage. If damage estimates are provided, often they are obtained from the NWS or the USACE.

FEMA has appointed special task forces to study particular major floods and recommend mitigation measures (for example, Interagency Hazard Mitigation Teams for each state affected by the 1993 Midwest flood). Their reports often contain damage estimates.

National Water Summary 1988-1989: Hydrologic Events and Floods and Droughts (USGS 1991) provides historical flood information for all fifty states through 1989. In particular, floods that are considered major historical events for each state are listed, including some damage estimates for individual floods.

## State Reports

State government agencies occasionally publish post-flood reports after particular flood events. To obtain additional, perhaps unpublished, information, we wrote to emergency management agencies in each state, asking them to provide information about historical flood damage. Five states were able to provide long-term historical summaries of their damaging floods, and these proved invaluable for analyzing the accuracy of the NWS estimates (see Section 5). Other states sent shorter-term information which provided useful examples.

## Unpublished NWS Damage Information

The NWS-HIC staff provided copies of their state and national flood damage data sets. These data sets included unpublished estimates for 1976-1982; however, the state and national estimates were found to be incompatible, as described in Section 3. Staff members also gave us access to the historical archives at their office in Silver Spring, MD. Two sets of files proved helpful in understanding how damage estimates were compiled in the past, and were used to supplement estimates for 1976-1982.

Monthly files for 1971-1995 contain the original flood reports from field offices all over the U.S., in no particular order. (These were discontinued when electronic submission of reports began in 1996.) The reports often contain descriptions of damage, but only occasionally provide damage estimates. They do not provide a basis for computing total damage by state or river basin.

Yearly files contain notes made by the people who compiled damage estimates, as well as news clippings and agency communications during the year. These are extremely helpful in developing estimates for 1976-1979, as they contain preliminary annual damage estimates with notes on when and where major floods occurred.

Articles on flash flood damage in 1978 and 1979, published in the journal Weatherwise (Marrero 1979, 1980), were written by José Marrero who had been responsible for collecting the flood damage data formerly published in Climatological Data, National Summary. These articles provide many of our state damage estimates for those years.

## E. Summary

The NWS effort to collect flood damage estimates has been remarkably consistent across the nation and over long time periods, resulting in the only source of long-term national flood damage information available in the United States. Similar procedures have been used to obtain estimates from field offices throughout the country, at least since 1950 and perhaps longer. Annual summaries were compiled using consistent methodologies and published in uniform formats during two extended periods, from 1933 through 1975, and from 1983 up to the present.

To create continuous time series of state and national damage estimates requires obtaining compatible estimates for the missing years, 1976-1982. It would also be desirable to base all the data on the same calendar, either fiscal years or calendar years. These tasks are addressed in Section 3.

The accuracy of the damage estimates is uncertain. Methods used to obtain the estimates suggest that they are often educated guesses. For many years they came primarily from newspaper reports. Today, short cuts are often used to extrapolate from a few good sources to make an estimate for an entire community. Evaluation of the accuracy of the estimates is undertaken in Sections 4 and 5.

## 3. DEVELOPMENT OF THE DATA SETS

The national data obtained from NWS consisted of annual total damage estimates for the U.S., including three territories: Puerto Rico (since 1975), the Virgin Islands (since mid-1980s), and Guam (since 1994). The state data contained annual damage estimates for each state and, in recent years, the three territories. In the national data, we subtracted estimates for the three territories from the U.S. totals to create a more uniform time series representing only the 50 states.

NWS estimates were spot-checked against those from other agencies. Estimates that appeared to be extremely large or small compared to published accounts of events were examined especially closely. In individual events that received follow-up study by the USACE, more accurate estimates were sometimes available. However, except during 1976-1982, there exists no compelling reason to change the NWS estimates or defer to another agency's estimates. Section 5 provides a quantitative assessment of uncertainty in the estimates and the implications for their effective use.

With a few important exceptions, the estimates presented as a result of this project have their origins in published NWS data. Obvious clerical errors have been corrected (see Section 4).

## A. Resolving the Data Gap, 1976-1982

To compile a complete time series of annual estimates required finding additional flood damage estimates for the years 1976-1982. As explained in Section 2, NWS ceased publication of annual flood damage summaries after 1975. Publication of comparable damage estimates did not resume until 1983, when USACE reports made damage estimates available again at the state and national levels, but not at the river basin level.

To make the state and national data sets as complete as possible, we focused on obtaining and evaluating estimates for 1976 through 1982. The NWS website (NWS-HIC 2001) included previously unpublished national flood damage estimates for 1976-1982, and an NWS spreadsheet included unpublished state estimates for that period. However, the national estimates and the state total estimates differed by large margins. An old, undocumented NWS computer printout tallied individual floods, by state, in the years 1976-1988, but we found it to be filled with errors and inconsistencies.

Despite a curtailment of effort, the NWS continued to compile some damage estimates during 1976-1979, which served as a starting point for our reconstruction attempts. We were able to develop estimates for 1976-1979 based on information in the NWS files and reports from other sources, as described in Appendix A.

Although we tried to reconstruct estimates for 1980-1982, there were not enough sources of information, either from NWS or other agency publications, to provide estimates for those years comparable to the data in the overall data set. Furthermore, there were some large disparities between estimates found in the NWS-HIC archives for the period 1980-1982 and damage estimates provided by states, leading us to conclude that some of the damage estimates
for this time period are highly unreliable (see Section 5). Therefore, estimates for 1980-1982 are not included in the reanalyzed data sets, and we judge that data published by NWS for this period is of consistently lower quality than in other years.

A few general comments can be made about 1980-1982. Flood damage descriptions in Storm Data, which were sparse in previous years, became even rarer in 1980-1981. The information that does exist for the period suggests that 1980 and 1981 were extremely dry years in most parts of the country, so flood damage was probably small compared to other years (Wagner 1982, USGS 1991, notes in NWS files). On the other hand, descriptions in Storm Data suggest that flood damage rose to a higher level in 1982, perhaps close to the average level of that time.

## B. Annual National Flood Damage Estimates (1926-1979, 1983-2000)

Since flood damage estimates for 1983 through 2000 are available only for fiscal years (October-September), it is desirable to compile the entire national flood damage data set using fiscal years. Fortunately, in its annual flood damage summary for 1975, Climatological Data National Summary (NWS 1977, vol. 13, p. 117) published national flood damage estimates by month for the years 1925 to 1975 . Therefore, we were able to calculate national annual damage totals based on fiscal years for 1926-1979, creating a consistent form for the full national data set.

Table 3-1 shows annual damage estimates for the United States, by fiscal year, in millions of current dollars and in millions of inflation-adjusted 1995 dollars. The implicit price deflator used to adjust for inflation is also shown in the table.

## C. Annual Flood Damage Estimates for the States (1955-1979, 1983-2000)

Annual damage estimates for each of the 50 states are given in Appendix B. The estimates for 1955 through 1975 are taken from Climatological Data National Summary (NWS 1977, vol. 13, p. 121), and are based on calendar years. Estimates for 1976-1979 are based on our reanalysis of available data (described above), and are presented by calendar year to be consistent with the earlier data. The estimates for 1983-2000 are taken from Army Corps of Engineers Annual Damage Report to Congress (1993, 2001), and are based on fiscal years (October-September).

## D. Annual Flood Damage Estimates in River Basins (1933-1975)

The NWS and U.S. Weather Bureau compiled annual damage estimates by river basin from 1933 through 1975, publishing them first in the Monthly Weather Review (1933-1947) and later in Climatological Data National Summary (1948-1975). To make these estimates accessible to users, we organized them by large river drainages in a uniform format for the full time period.

[^1]The basin-level damage estimates are available in spreadsheet form from our website, www.flooddamagedata.org. Estimates are presented by calendar year. The grouping of basins within drainages is somewhat different from that commonly used to define water resources regions (e.g., U.S. Dept. of Commerce, 1978 Census of Agriculture) because, over the years, the NWS sometimes changed its groupings. We developed uniform basin definitions for the full time period by using the following organizational system:
(1) Damages are grouped by drainage (e.g, St. Lawrence Drainage, Upper Mississippi, Great Basin) starting in the eastern part of the United States and moving towards the west coast, and then alphabetically by individual or grouped river basin(s).
(2) Often, the NWS grouped individual rivers together in annual summaries. For example, damage on the White and Wabash Rivers were usually included together as one estimate. If the published sources of flood data included damage for two river basins together in one year, then data for these two (or more) rivers were added together for all other years. This was the simplest way to produce a coherent data set that could be searched and produce just one row of data for one river basin.
(3) In many of the years, damage on unnamed streams was included. If the publication did not give a stream name, damage was included in a row for the drainage called "small streams."
(4) Sometimes the publications would include a river and its small tributaries together, by saying "X River and tributaries." When damage was published in this format, it was entered into the database under the river itself. So, damage listed for some rivers in some years may include not just the river, but its small tributaries (such as creeks).
(5) Creeks that were included separately in NWS publications from the rivers to which they are tributaries were entered into the database separately. Creeks can be differentiated from rivers in the database because they are labeled "Cr.," whereas rivers are entered with the river name only. An exception to this rule is for rivers with Spanish names, such as the Rio Hondo and Rio Grande. Since users may want to search for "Rio Hondo" rather than "Hondo," "Rio" is included in the database.
(6) Users looking for damage information on rivers with branches (such as North Platte, South Platte, and Platte) should look for each of these branches. In some cases, all of the branches of one stream are included together, and in some cases they are not.
(7) Several of the streams in the data set cross drainage boundaries. If there is a question about which drainage a stream is in, a user should look in both drainages.

## E. Use of the Damage Estimates

Users of these data sets should be aware that there is uncertainty in the damage estimates, with a likelihood of large errors in some estimates. Types of inaccuracy are described in Section 4, and the magnitude of errors is analyzed in Section 5. In consideration of uncertainty, recommendations regarding appropriate uses of the data are offered in Sections 6 and 7.

## 4. SOURCES OF INACCURACY IN THE DAMAGE DATA

Sections 4 and 5 analyze the accuracy of flood damage data received from the NWS Hydrologic Information Center. The goals are to (1) identify errors, inconsistencies, and uncertainties in the estimates, and (2) assess the accuracy of the estimates. The analyses focus on national and state annual damage estimates for the period 1955-1998.

Discussions with staff and comparison of the available materials revealed several sources of inaccuracy and inconsistency in the time series of historical damage estimates:

1. Clerical errors
2. Inconsistency in reporting over time
3. Low precision of reported estimates
4. Inadequate estimation methods

Each source of inaccuracy is described briefly below. Many of the clerical errors were correctable. Inconsistencies are inevitable in data collected over a long time period; their existence should be noted, but the effects are not measurable. Assessment of the inaccuracy introduced by poor estimation methods is undertaken in Section 5.

## A. Clerical Errors

These include mistakes in data entry, transcription, and labeling. Clerical errors were found and corrected, if possible, by comparing the data sets with published sources and material in the archive files. Mistaken labeling included, for example, the statement that all damages were summed by fiscal year (Oct. - Sep.) when, in fact, the national data had been summed by calendar year (Jan. - Dec.) through 1982.

## B. Inconsistency in Reporting over Time

Published NWS reports of flood damage are uniform in format and content for extended periods, leading us to assume that fairly consistent methods were used within the periods 19341979 and 1983-present (see Section 2). However, collection of flood damage data was greatly curtailed in 1980, then restarted in 1983 with a new purpose and less detailed reporting. Before 1980, the data were aggregated by river basin and calendar year with several types of flood loss itemized separately. After 1982, data were aggregated by state and fiscal year (Oct.-Sep.), at first with distinction between damage to property and crops, later with only the total of the two. The difference in data collection between the two periods introduces errors when one attempts to develop a uniform data series for the full timespan.

## Inconsistency in spatial units

Flooding naturally occurs in river basins, not necessarily bounded by individual states. When rivers form the state lines or floods cross state lines, assigning historical losses to the proper state is problematic. Our efforts to assemble estimates for 1976-1979 shed some light on the uncertainties involved. For example, the Wabash River rises in Indiana, but it forms a part of the border between Indiana and Illinois. NWS records on floods in 1976 and 1977 did not indicate how Wabash River flood damage should be divided between Indiana and Illinois; therefore, we had to decide the allocation arbitrarily. Another example is the Pearl River, which
rises in Mississippi and flows through Louisiana. The NWS reported high flood losses in 1979 in the Pearl River and adjoining basins, including parts of Alabama, but we could not accurately assign the damage among the three states. It is likely that similar uncertainties existed when the NWS converted 1955-1975 river basin damage estimates into state estimates. Thus, occasional mistakes in assigning damage to particular states should be expected.

## Inconsistency in time periods

NWS flood reports have usually been filed monthly, but aggregation periods have changed. Fiscal or calendar years are useful for accounting purposes; water years (which differ by geographic location) are more meaningful for scientific purposes. For example, NWS use of calendar years (through 1979) was problematic in aggregating data for locations along the Pacific coast. There, December - January is the peak flood season, leading to uncertainty in assigning damage to the correct year. (It appears that the NWS resolved this by assigning all the damage from a particular flood season to the year in which the hydrologic flooding peaked.) The present use of October - September fiscal years corresponds well to water years across the U.S, since fewer floods occur in the autumn dry season.

## Inconsistency in losses included

NWS policies on what kinds of losses to include have changed somewhat over the years. Damage estimates published through 1975 focused primarily on damage to property and crops, but included some indirect losses (loss of business and wages, 1934-1947; a "miscellaneous" loss category, 1948-1975). Since 1975, estimates routinely collected for Storm Data have been labelled only as property damage and crop damage. Present policy is to focus exclusively on physical damage to property and crops (John Ogren, NWS, personal communication, 8/29/01). However, the estimates come from diverse independent sources, so other types of damage could be included occasionally.

The NWS process of collecting damage data has always focused more attention on larger floods. Possible inconsistencies related to the exclusion of floods involving low damage are examined in Section 6.

It is sometimes impossible to separate damage by flood and other storm-related causes (e.g. wind, hail, snow, or ice). Typically, the full amount has been labeled as flood damage if heavy rain or river flows are considered to be the primary cause. Thus, NWS flood damage estimates are sometimes inflated by including other causes. Conversely, flood damage may be omitted when the major cause of damage is wind (hurricanes, tornadoes), snow, or ice. These uncertainties have existed throughout the entire data series and sometimes lead to incompatibilities with data from other agencies.

## C. Low Precision of Reported Estimates

The estimates have always been collected from myriad sources, differing greatly in precision and accuracy. Field office estimates sometimes include very precise figures; more often they give only one or two significant digits. Aggregated sums give a misleading impression of greater precision. For example, separate estimates of $\$ 7$ million, $\$ 400,000$, and $\$ 17,000$ add to a more precise-looking annual estimate of $\$ 7,417,000$ but the accuracy is limited by that of the largest estimate ( $\$ 7$ million, in this case).

Even one-digit accuracy is not assured. Published reports sometimes disagree greatly on the amount of damage in a particular flood event. For example, shortly after the failure of the Teton Dam in Idaho in 1976, damage estimates ranged from $\$ 400$ million to $\$ 1$ billion (Chadwick et al. 1976). In subsequent reports from several agencies, the $\$ 1$ billion estimate was used repeatedly with no further refinement (for example, USACE Walla Walla District 1977). A final report on the Teton Dam failure (Eikenberry et al. 1980) gave the only specific figures: loss of a $\$ 102.4$ million project investment and over $\$ 315$ million paid to more than 7,500 claimants. This establishes a minimum loss of about $\$ 417$ million, but only covers a portion of the total damage. In creating the reanalyzed data set, we chose to use the geometric mean of the minimum and maximum estimates, producing a damage estimate of $\$ 650$ million.

After NWS reports on flood damage were discontinued in 1980, Storm Data became the primary source of flood damage estimates (see Section 2). From 1980 until about 1984, the accuracy of available estimates is limited by Storm Data reporting procedures. At that time, NWS field offices reported damage estimates by checking categories on the following logarithmic scale:

1 Less than $\$ 50$
$2 \quad \$ 50$ to $\$ 500$
$3 \quad \$ 500$ to $\$ 5,000$
$4 \quad \$ 5,000$ to $\$ 50,000$
$5 \quad \$ 50,000$ to $\$ 500,000$
$6 \quad \$ 500,000$ to $\$ 5$ million
$7 \quad \$ 5$ million to $\$ 50$ million
$8 \quad \$ 50$ million to $\$ 500$ million
$9 \quad \$ 500$ million to $\$ 5$ billion
Such estimates indicated only the order of magnitude of the damage (e.g. roughly a $\$ 100,000$ flood, a $\$ 1$ million flood, a $\$ 10$ million flood). Occasionally, more specific damage estimates were included in narrative descriptions of a flood event.

To add a set of these categorical estimates, each category must be assigned a point value. Proportional errors are minimized by using the geometric mean of a category's end points. That is, category $k$ is from $\$ 0.5 \times 10^{k}$ to $\$ 5 \times 10^{k}$ (when $k>1$ ), so the best estimate is

$$
(2.5)^{0.5} \times 10^{k}=1.58 \times 10^{k} .
$$

However, the individual estimates could be in error by more than a factor of 3. For example, an event with damage originally estimated anywhere between $\$ 500,000$ and $\$ 5$ million would be entered into the data set as damage of $\$ 1.58$ million. This is about 3 times higher than an estimate at the low end of the range, and about $1 / 3$ of an estimate at the high end of the range.

Errors associated with these logarithmic categories are of concern primarily in the 19801984 flood damage estimates. By 1985, it appears that NWS-HIC had instituted some follow-up checking and refinement of the estimates, at least for major floods. Use of logarithmic categories in Storm Data was discontinued in 1995. Since then, one- or two-digit estimates have been given in thousands or millions of dollars (e.g. $\$ 60 \mathrm{~K}$ or $\$ 3.2 \mathrm{M}$ ).

## D. Inadequate Estimation Methods

Potentially the most serious source of inaccuracy is the ad hoc approach to obtaining damage estimates from each NWS field office (described in Section 2). The estimates are collected by staff members who have little or no training in damage estimation and who rely on diverse sources. Estimation methods used by their sources are unknown, and completeness of coverage varies. Estimates are usually obtained within 2 months after a flood event and are not compared by the NWS with records of actual damage.

## Incomplete reports and omissions

A state emergency management official (Kay Phillips, Ohio Emergency Management Agency, personal communication, 7/25/00) complains that the NWS calls her asking for a damage estimate within a few weeks after a disaster. At that time, the extent of damage is unknown and emergency managers are scurrying to respond to immediate needs. They have some knowledge of losses to individuals, but little knowledge of damage to infrastructure, which makes up a large part of total losses. Thus, in her opinion, early loss estimates tend to be much too low in relation to final tabulations.

An example of underestimation is the NWS damage estimate for California flooding associated with Hurricane Kathleen in 1976. The NWS dataset (which had not been fully updated because annual summaries were discontinued that year) gave a damage estimate of \$42 million, whereas estimates in subsequent published reports (e.g., Montane 1999) are 3 to 4 times higher.

Errors of omission occur when a significant flood event is overlooked entirely. For example, flash floods in California in July 1979 caused damage estimated at \$26-50 million (Montane 1999), but the NWS dataset reported no damage.

## Potential biases

A substantial bias toward underestimation is expected due to incomplete reporting and omission of some floods. However, we hypothesize that some damage estimates provided to the NWS field offices might be biased upward if, for example, losses were exaggerated to improve chances of getting state or federal assistance. Accuracy and bias in early damage estimates are examined in Section 5.

## 5. ACCURACY OF DAMAGE ESTIMATES

In general, estimates of damage contain a high degree of uncertainty. Ideally, estimation errors would be measured by systematically comparing estimates with actual costs, which often are not known until long after a flood event. Unfortunately, actual cost data are seldom collected in a form that can be compared with estimates made at the time of the flood. This section examines the accuracy of flood damage estimates in two ways: (1) by comparing estimates with actual costs in one large flood disaster, and (2) by comparing pairs of estimates from different sources for many flood events.

## A. Errors in Early Damage Estimates

NWS flood damage estimates are usually compiled within three months after a flood event, long before the actual costs can be known. Until recently, even in serious disasters, actual total damage costs were not systematically compiled by any agency. There was no way of checking the accuracy, or even the reasonableness, of most damage estimates.

In recent years, however, FEMA has systematically collected cost data for the programs it administers - admittedly only a fraction of total disaster costs. Beginning in 1992, FEMA instituted a computerized system for recording and tracking applications for federal assistance in presidentially declared disasters. State and county governments have gradually developed the capabilities to link to this system. The damage estimates submitted by local officials to FEMA probably represent the best available early estimates under disaster conditions. A team visits each damage site to view the extent of losses and make preliminary estimates. Thus, in some disasters and some jurisdictions, it is now possible to systematically compare early damage estimates with actual costs. Data from FEMA's Public Assistance Program are particularly appropriate for our purposes because a large portion of the losses involve physical damage to property. Public assistance covers damage to public facilities such as roads and bridges, schools, government buildings, and nonprofit agencies.

In the aftermath of a natural disaster, damage information is assembled according to guidelines established by FEMA. The following stages are described by FEMA (1998) and Michael Sabbaghian ${ }^{1}$ of the California Office of Emergency Services (OES) (personal communication 8/30/00).
(1) Initial Damage Estimate (IDE): Local officials provide estimates of physical damage based on early reports and descriptions, without necessarily visiting the damage sites.
(2) Preliminary Damage Assessment (PDA): A team including local, state, and FEMA officials visits the damage sites to do a "windshield estimate," perhaps viewing the sites from a car window or walking around. The PDA estimates are used to decide whether federal assistance is needed. If so, they are submitted to FEMA as part of the governor's request for a presidential disaster declaration.

[^2](3) Damage Survey Report (DSR): Applicants submit requests for public assistance with detailed worksheets estimating the cost of repairs. FEMA or the state perform inspections (physical surveys) for each large project and "verify documentation on a portion of the small projects" (FEMA 1998). The DSR is used to obligate federal and state disaster assistance funds. The DSR obligations change as bids are received to accomplish the repair work, and computer records are updated accordingly.
(4) Actual Cost: Final total costs when all projects are completed and the DSR is closed. For large disasters, closure might not occur until 4 to 5 years after the disaster event.

Descriptions of the NWS procedures for obtaining flood damage estimates suggest that, in most cases, the estimates have been qualitatively similar to the IDE and certainly no better than the PDA. Indeed, NWS field offices obtain some of their estimates from FEMA's survey teams (Section 2). Only in the largest floods (notably, the widespread flooding of the upper Mississippi basin in 1993) have extensive efforts been made to update the damage estimates over an extended period.

Therefore, to estimate the errors in early damage estimates that can be expected under good conditions (that is, from officials who have systematically viewed the damage), we use FEMA records from a recent flood disaster as a case study. In February 1998, winter storms with heavy rains led to widespread flooding in California. The president declared a major disaster in 41 counties, designated the "1998 California El Niño" disaster (FEMA-1203-DR). Table 5-1 shows the IDE and PDA estimates for each county under the public assistance program. It also shows the funds that had been obligated in the FEMA database as of June 1, 2001. Although the DSR has not been closed at the time of this writing, it is expected that nearly all costs have been obligated; therefore we will treat these figures as the "actual costs."

The bottom line of Table 5-1 shows that total public assistance costs in the state were approximately $\$ 316$ million. The PDA underestimated the total costs by only $6 \%$ ( $\$ 19$ million). Because no IDE was provided for several counties, the total IDE of $\$ 240$ million should be compared with the total actual cost of $\$ 279$ million from the matching 33 table entries. On that basis, the IDE underestimated total costs by about 14\% (\$39 million).

Estimates for smaller units (individual counties and the "state agencies" category) are much less accurate, however. Errors in the IDE are particularly large, ranging from underestimation by $\$ 26$ million ( $82 \%$ ) in Los Angeles County to overestimation by $\$ 20$ million ( $316 \%$ ) in San Benito County. In the PDA, errors range from underestimation by $\$ 16$ million (52\%) in the state agencies category to overestimation by $\$ 23$ million (304\%) in San Bernardino County.

Table 5-1. California 1998 El Niño Disaster: Estimated and actual public assistance costs, in thousands of current dollars.

| County | al | IDE |  | PDA |  |
| :---: | :---: | :---: | :---: | :---: | :---: |

[^3]Figures 5-1(a,b) show scatterplots of (a) the IDE vs. actual costs and (b) the PDA vs. actual costs. Logarithmic scales are used on the axes to highlight proportional differences between estimates and actual costs. The solid diagonal line represents perfect agreement. Data points outside of the two dashed lines are cases in which the estimate differs from the actual costs by more than a factor of two. Clearly the IDE is less accurate than the PDA: the points are much more scattered. (Correlations between the logs of estimates and actual costs are $r=0.46$ for the IDE and 0.88 for the PDA.)

Since the Initial Damage Estimates are based on rather superficial damage descriptions, it is not surprising that large errors are the norm: Over half of the IDEs (18 out of 33) are off by at least a factor of two, and 13 of them are off by more than a factor of four. As a percentage of the actual costs, the IDE errors can be enormous, ranging from a $99.5 \%$ underestimate in Santa Barbara County to a $2170 \%$ overestimate in Tehama County. The Preliminary Damage Assessments are somewhat better, yet over one-third ( 15 out of 42) are off by at least a factor of two and 3 of them are off by more than a factor of four. The PDA errors range from a $77 \%$ underestimate in Humboldt County to a $393 \%$ overestimate in Yolo County.

The population of some California counties exceeds that of many small states. So estimation errors in the larger counties are indicative of the error levels to be expected in many states. For example, Los Angeles County, with a 1990 population of 8.9 million, is larger than 42 of the states. Table $5-1$ shows that, in this disaster, the IDE underestimated actual costs by $82 \%$.

To check for systematic bias in these early damage estimates, we used a statistical pairedcomparison test. A systematic tendency to underestimate might be expected if some types of damage cannot be observed without careful inspection. On the other hand, we wondered if there might be a tendency for local officials to overestimate damage in order to increase the chance of being considered for federal aid. The IDE and PDA estimates were compared with actual costs, as follows:

Let $e_{i}=$ estimated damage, $a_{i}=$ actual cost. We wish to test the null hypothesis that the geometric mean of $e_{i} / a_{i}=1$. This is equivalent to the hypothesis that mean $\left[\log \left(e_{i}\right)-\log \left(a_{i}\right)\right]=0$. We tested the hypothesis twice, first letting eiresent the IDE values in Table $5-1(\mathrm{~N}=33)$, then letting $\mathrm{e}_{\mathrm{i}}$ represent the PDA values $(\mathrm{N}=42)$. A $t$-test is appropriate, even in these small samples, because the sample values $\log \left(\mathrm{e}_{\mathrm{i}}\right)-\log \left(\mathrm{a}_{\mathrm{i}}\right)$ are approximately normally distributed. For the IDE, $\mathrm{t}=-1.27$, and for the PDA, $\mathrm{t}=-1.10$, neither of which is statistically significant at a 95\% confidence level. Though there may be a tendency to underestimate the amount of damage, the bias is not statistically significant.

In summary, this example indicates that positive and negative estimation errors tend to average out when estimates are highly aggregated in a large flood event (over $\$ 300$ million damage in 1998 dollars, in this case). The initial rough estimates (IDE) tended to underestimate actual damage and the more careful PDA estimates were reasonably accurate. It shows, however, that in smaller flood events (\$30 million damage or less in 1998 dollars), which involve substantially less aggregation, the errors can be extremely large. Half of the PDA estimates

Flood Damage Estimates in California 1998 El Nino Disaster (millions of dollars)

Initial Damage Estimate (IDE)

Figure 5-1. Estimated flood damage in California counties in the 1998 El Niño disaster, compared with actual costs as of June 1, 2001: (a) Initial Damage Estimate.

Flood Damage Estimates in California 1998 El Nino Disaster (millions of dollars)

Preliminary Damage Assessment (PDA)

Figure 5-1, continued. (b) Preliminary Damage Assessment.
were in error by more than a factor of 1.5 ; and half of the IDEs were in error by more than a factor of 2 (with many off by more than a factor of 4).

Given the methods used by NWS field offices to obtain flood damage estimates (described in Section 2), it is unlikely that the NWS estimates are much better than the IDEs examined here. Thus, when an annual flood damage estimate for a state is less than about $\$ 30$ million, one should not expect the NWS estimate to depict actual losses accurately. However, the above analysis does not indicate systematic bias in the individual estimates, and errors tend to average out when the estimates are summed.

From the above results, we conclude that aggregation of many damage estimates in floods that have caused high levels of damage ( $\$ 300$ million or more in 1998 dollars) provides reasonably good estimates of total damage. However, estimates at a low level of aggregation ( $\$ 30$ million or less) often are in error by factors of 2 or more. Such small estimates should be used with great caution: Direct comparisons of individual estimates are likely to be misleading.

## B. Comparison of Damage Estimates from NWS and States

Appropriate data are not available for comparing NWS estimates with actual flood damage costs. However, comparable estimates are available from independent state sources to do an assessment of typical estimation variability.

Every state in the U.S. has an emergency management agency. In July 2000, we wrote to the head of the emergency management agency in each state asking for historical data on flood damage in their state. The letter was followed by a phone call to the appropriate administrator if a response was not received within three weeks. Twenty-one states responded ${ }^{2}$, but many of them could provide damage information only after 1990 and only related to losses covered by FEMA. Five states either had published historical summaries of flood damage or were able to compile flood damage estimates from their files covering at least 20 years which were based on criteria similar to those used by the NWS.
(1) California: A report (Montane 1999) describes disasters from 1950 through 1998 including for each disaster a brief description, general location, estimated damage, number of deaths, and whether a presidential disaster declaration was issued. We selected the disasters that involved flood, heavy rainfall, or severe storms for this comparison.
(2) Colorado: The state has formally collected flood data since 1937. A report (McLaughlin Water Engineers, Ltd. 1998) summarizes flood history and provides damage estimates for major floods since 1864.
(3) Michigan: A report (Michigan Dept. of State Police 1999) summarizes the 14 floods during 1975-1998 that resulted in a disaster declaration by either the governor or the president. Damage estimates are given for all of the floods that received a presidential declaration and four that received only a gubernatorial declaration.
(4) Virginia: Damage estimates in presidentially-declared flood disasters during 1977-1999 were provided by Michael Cline, State Coordinator of the Virginia Dept. of Emergency

[^4]Services (personal communication 2000).
(5) Wisconsin: One report on the 1993 Midwest flood summarizes flood losses in Wisconsin from 1973 through 1992 (FEMA 1993), and another report provides loss estimates for the 1993 flood (Wisconsin Dept. of Natural Resources 1993).

In the state reports, the loss estimates are provided for each major flood event, sometimes with two or more events occurring in a given year. To match the annual loss estimates provided by NWS-HIC, we added up the flood losses in each state for each year, using calendar years during 1955-1982 and fiscal years (Oct-Sep) during 1983-1998 to match the time periods used in the NWS estimates. ${ }^{3}$ Our comparison covers a total of 155 years in the 5 states: 44 years each in California and Colorado (1955-1998), 24 years in Michigan (1975-1998), 22 years in Virginia (1977-1998), and 21 years in Wisconsin (1973-1993).

Of course, the state estimates are subject to the same types of error as the NWS estimates - neither is assumed a priori to be more accurate. The intent of this section is to investigate large discrepancies between estimates from different sources in order to understand how estimates of the same event vary and to determine whether some floods are overlooked. In the following analysis, all loss estimates are reported in inflation-adjusted 1995 dollars.

## When estimates are very low or missing

Table 5-2 provides a comparison of the estimates in all 155 years, with cases along the diagonal (from upper-left to lower-right) showing the closest agreement. An obvious difference between the NWS and state estimates is in the amount of missing data - a result of different purposes of the data. NWS flood loss estimates are collected every year, with relatively small losses included; hence, estimates are missing or zero in only 28 years and are below $\$ 5$ million in 56 years. In contrast, the state reports focus on more serious floods, so years of relatively low flood loss are not included. The states did not report losses in 91 cases, and included losses below $\$ 5$ million in only 6 cases. ${ }^{4}$ The threshold for reporting appears to be somewhat higher in California, where the lowest reported loss was $\$ 15$ million.

We conclude that these five states do not attach great importance to floods that cause less than $\$ 5$ million in damage; therefore, annual losses below that threshold will be described as "low" flood losses. Lumping the low and missing categories together, the NWS and states agree that 78 ( $50 \%$ ) of the 155 cases involved little or no flood damage. Disagreements arise, however, when at least one estimate is above $\$ 5$ million.

[^5]Table 5-2. Crosstabulation of flood damage estimates from the NWS and five states. Estimates are in millions of $\mathbf{1 9 9 5}$ dollars.

Disagreement \#1: State estimate above $\$ 5$ million, NWS estimate missing or low. California describes flood losses of $\$ 50$ million in 1979 and $\$ 15$ million in 1984, both years in which the NWS provides no loss estimate. In addition, states claim moderate losses in four years when the NWS estimate is low (<\$5 million): Colorado 1969 and 1983 ( $\$ 20$ and $\$ 24$ million, respectively), California 1972 ( $\$ 29$ million), and Virginia 1998 ( $\$ 13$ million). Because these floods were cited as significant in the state reports, it seems likely that the damage was considerably greater than the NWS estimates would indicate. The differences between estimates range from a factor of 6 in the 1998 Virginia case to a factor of 169 in the 1983 Colorado case.

Out of 84 cases in which the NWS indicated flood losses were low or missing, 78 (93\%) were in reasonable agreement with the state reports; but 6 cases in which over $\$ 5$ million damage was claimed by a state were either overlooked entirely by the NWS or underestimated by a large factor.

Disagreement \#2: NWS estimate above $\$ 5$ million, state estimate missing or low. The top row of Table 5-2 shows 17 cases, not mentioned in the state reports, in which the NWS indicates flood losses over $\$ 5$ million. In all but one case, the NWS estimate is below $\$ 51$ million. We assume that some flood damage probably occurred, but the state did not include it in their report. Four of these cases are in Virginia and would have been omitted because they did not receive a Presidential disaster declaration. Excluding Virginia, the three largest NWS estimates are for California, where flood losses are generally high and a $\$ 50$ million loss might be considered relatively unremarkable.

In one case, however, the NWS estimate is very high: \$806 million in Michigan in 1981. This is contradicted by Michigan's report (Michigan Dept. of State Police 1999), which lists eight floods since 1975 and describes the 1986 flood (with losses of about $\$ 400$ million) as the most damaging, but makes no mention of a flood in 1981. This blatant error casts doubt on the NWS estimates for 1980-1982, which were derived from broad damage categories in Storm Data, apparently with little or no verification. (See also Section 3 on 1980-1982 damage estimates.)

## Comparisons of estimates

For California, Figures 5-2(a,b) show cases in which at least one estimate is greater than $\$ 50$ million. For the other states, Figures 5-2(c-f) show cases in which at least one estimate is greater than $\$ 5$ million. Visually, the graphs are dominated by the major floods (over $\$ 500$ million), where most of the disagreements appear to be relatively small (except for the erroneous estimate we have already noted for Michigan in 1981). At the moderate-to-high damage levels ( $\$ 5-500$ million), however, some differences are proportionately large. For example, estimates differ by more than a factor of two in California in 1965, 1973, 1976 and 1993, Colorado in 1984 and 1995, Michigan in 1982 and 1998, Virginia in 1979, 1984, 1992 and 1996, and Wisconsin in 1973, 1978, 1980 and 1986.

## CALIFORNIA

 1955-1977

MICHIGAN
1975-1998

Figure 5-2, continued. (d) Michigan, 1975-1998.

## VIRGINIA <br> 1977-1998

Figure 5-2, continued. (e) Virginia, 1977-1998.

WISCONSIN
1973-1993

Figure 5-2, continued. (f) Wisconsin, 1973-1993.

Figure 5-3 is a scatterplot of all cases that have estimates from both NWS and the state. Logarithmic scales are used on the axes to highlight proportional differences in the estimates. The solid diagonal line represents perfect agreement between the estimates. Data points outside of the two dashed lines are cases in which the estimates differ by more than a factor of two. Seventeen cases are above the upper dashed line, representing state estimates more than twice as large as the NWS estimate. Six cases are below the lower dashed line, with NWS estimates more than twice as large as the state estimate.

The closest agreement between state and NWS estimates occurred in floods involving major damage (over $\$ 500$ million). At the other extreme, the largest proportional disagreements (cases farthest outside the dashed lines) occurred when both sources indicated that flood damage was low or moderate (under $\$ 50$ million).

From the standpoint of the NWS estimates, when the NWS damage estimate was: (1) moderate ( $\$ 5-50$ million), then $55 \%$ of state estimates differed by a factor of 2 or more; (2) high ( $\$ 50-500$ million), then $30 \%$ of state estimates differed by a factor of 2 or more; (3) major (over $\$ 500$ million), then none of the differences exceeded a factor of 1.4.

There are many plausible explanations why agreement might improve as total damage increases. First, the crisis of a major flood spurs studies by numerous agencies. Collection of damage information is more likely to be systematic and complete in a major flood than in a smaller one. Second, agencies are more likely to share information about major floods (which would lead to increased agreement, but does not guarantee greater accuracy). In smaller floods, on the other hand, collection of damage information is likely to be haphazard and there is less interest in checking and correcting early damage estimates. Third, the damage in large floods is aggregated from many individual damage estimates so that random errors tend to cancel out. Small floods involve less aggregation and, hence, relatively larger errors.

## C. Accuracy: Summary and Conclusions

The following conclusions are drawn from the analysis of accuracy and consistency presented in Sections 4 and 5.

1. The collection and processing of flood damage data by the NWS has been reasonably consistent from 1934 to the present, except during the period 1976-1982. Errors are probably somewhat larger in the first few years after data collection resumed in 1983.

Data from NWS files and other sources made it possible to reconstruct state and national flood damage estimates for 1976-1979. However, little data was collected during 1980-1982 and large errors were discovered in estimates developed later for that period. As a result, the years 1980-1982 have been excluded from the reanalyzed data sets. Annual compilation of damage estimates resumed in 1983, but depended mainly on information from Storm Data in the first few years. Particularly in 1983-1984, omissions are more likely and estimates probably contain somewhat larger errors because of the use of damage categories.

## Flood Damage Estimates in Five States (millions of 1995 dollars)

State Estimate

Figure 5-3. Scatterplot of National Weather Service flood damage estimates vers us estimates obtained from five states, in millions of 1995 dollars.
2. Individual damage estimates for small floods or for local jurisdictions within a larger flood area tend to be extremely inaccurate.

It is rare to have actual cost data to compare with damage estimates. The above analysis of one large flood disaster indicates that, in cases where actual costs are less than $\$ 30$ million, a large proportion of estimates are off by at least a factor of two and sometimes much more. When damage in a state is estimated to be less than $\$ 50$ million, estimates from NWS and other sources frequently disagree by more than a factor of two.
3. Damage estimates become more accurate at higher levels of aggregation. Thus NWS estimates totaled over large geographic areas or many years are likely to be fairly reliable (within about a $50 \%$ margin of error).

Errors tend to average out, as long as the local estimates are not systematically biased. For example, the sum of estimates from many counties in a large flood area are found to be quite close to the actual total costs for the area as a whole. When damage in a state is estimated to be greater than $\$ 500$ million, disagreement between estimates from NWS and other sources are relatively small ( $40 \%$ or less). The relatively close agreement between NWS and state estimates in years with major damage is reassuring, since the most costly floods are of greatest concern and make up a large proportion of total flood damage.
4. Floods causing moderate damage are occasionally omitted, or their damage greatly underestimated, in the NWS data sets.

When discrepancies between NWS and state estimates are large, most often the state estimate is the higher one. Occasionally, NWS estimates are missing for floods in which the state claims as much as $\$ 50$ million damage. Such omissions would have little effect on national total damage estimates. However, they might be important in analyses of damaging floods at the state or river basin level. Researchers studying flood damage in states or river basins should be aware that the NWS estimates occasionally overlook some locally significant damage.

## 6. DEALING WITH DATA OMISSIONS AND INCONSISTENCIES

Used appropriately, reanalyzed NWS damage estimates can provide valuable information about historical flood damage in the U.S. But users should be aware of the deficiencies in the damage data sets and choose methods of analysis that guard against misleading results. Omissions and inconsistencies are of particular concern if they introduce systematic biases in the damage estimates that might distort comparisons of flood damage between different time periods or locations. This chapter examines frequency distributions of state damage estimates to evaluate the impact of omissions and inconsistencies and to suggest appropriate methods of analysis.

## A. Frequency of Damaging Floods at the State Level

Few states report flood damage every year; indeed, many states experience damaging floods rather infrequently. In studying the flood damage history of a state or region, it is of interest to know how often damaging floods occur. However, the lack of a damage estimate does not necessarily imply zero flood damage because reporting of dollar damages, particularly in small flood events, is somewhat unreliable. To assure consistent comparisons across different times and locations, it would be helpful to know what levels of damage have been reported fairly consistently.

The NWS defines its flood damage data as "loss estimates for significant flooding events" (NWS-HIC 2001). Floods that cause deaths or extensive damage have always received the most attention, but the records do not indicate any formal criteria on which floods to include. When small estimates are submitted, NWS-HIC has usually included them in the damage totals. (An exception occurred during 1993-1998, when local damage estimates below $\$ 50,000$ were not entered in the flood damage database.) However, field office reports often mention damage without providing dollar estimates. When pressed for a definition of which floods are "significant" enough that intensive efforts are made to obtain complete estimates, NWS-HIC Director Frank Richards offered a rough guideline of at least $\$ 1$ million in losses (personal communication, 6/27/01). This applies to NWS practice since 1990, but earlier guidelines, if used, are unknown.

Frequency distributions of state flood damage estimates suggest that floods with total state damage less than $\$ 100,000$ (in 1995 dollars) have often gone unreported, and those under $\$ 1$ million also have sometimes been omitted. Figure 6-1 shows the distribution of all state flood damage estimates in recent years (1983-1999) and in an earlier period (1955-1978). Estimates were missing nearly $30 \%$ of the time in the earlier period, and only $16 \%$ of the time in recent years. This could imply either fewer damaging floods or different reporting standards in the earlier period - perhaps both. Because the early period had a high frequency of flood damage over $\$ 1$ million, it is unlikely that the incidence of damage less than $\$ 1$ million was as small as the distribution suggests. It is likely that lower level damages were not consistently reported before 1980.

## Frequency Distribution of Annual State Damages

## During Two Periods

Percent of Years in Period

Figure 6-1. Frequency distributions of annual state flood damages (1995 dollars), 19551978 and 1983-1999.

For determining the frequency of damaging floods, we recommend establishing a threshold above which damage estimates are expected to be provided consistently. In our analysis we have chosen to use the frequency of inflation-adjusted state flood damage estimates above $\$ 1$ million.

## B. Magnitude of Damages

Individual states differ greatly, both in flood frequency and in the magnitude of damage in a "typical" flood event. Figure 6-2 shows, for each state, the estimated total damage during the years 1955-1978 and 1983-1999, as well as the damage in the worst flood year. A few states have had many major floods (e.g. California, Texas). Many others have suffered most of their total damage in just one or two major flood events (including Pennsylvania and Iowa, among the worst in total damage). Many states had no yearly damage greater than $\$ 500$ million in this period, and there are 10 states whose total damage for the entire 41-year period is less than $\$ 500$ million.

These state comparisons do not include 1979 damage estimates because some estimates for that year are available only for large regions, not for individual states (see Section 3). Estimates of 1979 damage are available for many states, however, and are useful to illustrate how rankings of states by total damage can differ depending on the time period covered. For example, 1979 flood damage in Texas was $\$ 3.76$ billion - substantially greater than in any of the years included in Figure 6-2. Texas would move from $6^{\text {th }}$ to $3^{\text {rd }}$ place in the rankings if 1979 were included.

The frequency distributions of flood damage in each state give another perspective on past flood vulnerability. Table $6-1$ shows how states differ in both frequency and severity of damaging floods during 1955-1978 and 1983-1999. The states are ordered by their median annual flood damage based on all 41 years, including years with no reported damage. The number of missing, very low (<\$1 million) and relatively high (> $\$ 100$ million) damage estimates are shown to indicate both frequency and relative magnitudes of flood damage. Three "historical vulnerability categories" can be loosely defined to illustrate the differences between states. (Although the worst flood, indicated by maximum damage, is shown for each state, it is not considered in defining historical categories.)
(1) Low vulnerability: Floods are relatively infrequent, and damage is less than about $\$ 2$ million in the majority of years (1995\$). Includes New England states, some mid-Atlantic coastal states, low-population states in the arid west, plus Hawaii and Alaska. Damage rarely exceeds $\$ 100$ million. (Frequency distributions of flood damage in Maine and New Mexico are surprisingly similar, despite their geographic differences.)
(2) Medium vulnerability: Damaging floods occur in most years, and median damage is in approximately the $\$ 2-8$ million range (1995\$). Includes most states in the southeast, the lower Mississippi basin, and the Pacific northwest. Most of these states have few instances of flood damage over $\$ 100$ million. (Louisiana is a notable exception.)
(3) High vulnerability: Damaging floods occur in most years, and damage exceeds about $\$ 8$ million in the majority of years (1995\$). Includes states in the upper Mississippi, Missouri,

[^6]and Ohio basins, parts of the mid-Atlantic region, California and Texas. Flood damage over $\$ 100$ million occurs relatively frequently, especially in Missouri, California, and Texas.

Perception of flood damage in a state is influenced by historical experience. A state's median damage can be taken as the expectation of the flood damage threat in a "typical" year, its maximum damage as the public view of a "major flood". These categories are useful in describing how state perspectives on flood damage might differ. Although some states in each category have experienced massive flood damage (over, say, $\$ 1$ billion), such damage occurs most frequently in the high vulnerability category.

One might expect that reporting of flood damage by NWS field offices would be influenced by the flood history of an area. In low vulnerability states, floods causing over \$1 million damage are notable events and seem unlikely to go unreported. Conversely, in high vulnerability states, damage of $\$ 5$ million or more occurs frequently so smaller damages might seem unremarkable and be easily ignored.

However, the analysis in Section 5 indicates that these expectations are false. In California, a high vulnerability state, the NWS often reports damage under $\$ 5$ million, but no NWS estimates were provided in two years when the state claimed substantial damage (1979 and 1984). ${ }^{5}$ Likewise in Colorado, a low vulnerability state, damage of $\$ 24$ million went virtually unreported in 1983 (the NWS estimate is $\$ 140,000$ ). From these examples and others in Section 5 , we conclude that omissions of estimates in the $\$ 5-25$ million range in the NWS data sets are not systematically related to the size of a state or its typical damage level; rather, the omissions can be considered random inconsistencies in data collection operations.

## C. Implications for Analysis of State Damages

States typical of the three vulnerability categories are shown in Figures 6-3(a-c) and Table 6-2. California represents the high vulnerability states, Alabama the medium vulnerability states, and Maine the low vulnerability states. In all three states, damage totals for the full 41 year period (Table 6-2) would be affected little by occasional omission of damage under $\$ 1$ million. Indeed, California and Alabama totals would be affected little by a few $\$ 25$ million omissions. But in Maine, a $\$ 25$ million flood is relatively large, representing over $10 \%$ of total damage. Its omission could greatly influence the result of, say, a comparison of damages during two time periods. Furthermore, since floods in Maine involve relatively low damage there is less aggregation of damage estimates, therefore less tendency for errors to average out.

For low vulnerability regions, we recommend spatial aggregation to reduce the impact of errors and omissions. Several contiguous regional groupings of states with similar frequency distributions are suggested in the second column of Table 6-1. For example, estimates of damage in New England are expected to be more reliable than estimates of damage in Maine. Other groupings might be appropriate depending on the purpose of a particular analysis.

[^7]Table 6-2. Levels of annual state flood damage in three states, during all years, 1955-1978 and 1983-1999.

| Annual State Flood Damage Level | Flood Damage Estimates (Millions of 1995 dollars) |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | California <br> (High Vulnerability) |  | Alabama (Medium Vulnerability) |  | Maine <br> (Low Vulnerability) |  |
|  | N | Sum of Damages | N | Sum of Damages | N | Sum of Damages |
| Over \$1 billion | 3 | 5,008.4 (47.4\%) | 0 | - | 0 | - |
| \$100-1,000 million | 10 | 4,873.8 (46.1\%) | 3 | 601.86 (59.6\%) | 0 | - |

Figure 6-3, continued. (b) Medium vulnerability, Alabama.
(c) Maine Flood Damage

Figure 6-3, continued. (c) Low vulnerability, Maine.

## D. Recommendations

In summary, the following two procedures are recommended to reduce the impact of errors and omissions in the NWS state damage estimates:

1. To determine the frequency of damaging floods in a state, establish a threshold above which damage estimates are consistently provided and report the number of floods that have exceeded the threshold. Our analysis indicates that reporting of state flood damages greater than $\$ 1$ million (in 1995 dollars) has been reasonably consistent since 1955, although state damages in the $\$ 1$ - 50 million range prior to 1990 occasionally went unreported.
2. To reduce the impact of errors and omissions in the estimates, increase the level of aggregation; this can be done either by (a) using total damages in a state or states over an extended period of years, or (b) computing damages for multi-state regions rather than using individual states. This is especially important for statistical analysis of low vulnerability states.

## 7. USE AND INTERPRETATION OF NWS FLOOD DAMAGE DATA

"Estimate" is the key word for describing the NWS flood damage data. They do not represent an accurate accounting of actual costs, nor do they include all of the losses that might be attributable to flooding. Rather, they are rough estimates of direct physical damage to property, crops, and public infrastructure. Damage estimates for individual flood events are often quite inaccurate, but as estimates from many events are added together the errors become proportionately smaller.

These findings suggest that, at the national level, annual damage totals are reasonably accurate because they are sums of damage estimates from many flood events. Flood damage occurs every year, and the frequency distribution of national damages during 1934-1999 approximates a log normal distribution. Therefore, the national data can be analyzed using conventional parametric statistics.

State annual damage estimates are more problematic. Both frequency and magnitude of damage must be considered, because damaging floods do not occur every year in most states. Flood frequency cannot be determined simply by the presence or absence of a damage estimate because reporting, particularly for small floods, is unreliable. (To estimate flood frequency, we recommend establishing a threshold below which estimates are simply classified as "low" or "minimal", as in Section 6.) Estimates of the magnitude of annual damage are often highly unreliable. In many states, most of the annual damage estimates are below $\$ 500$ million (in inflation-adjusted 1995 dollars), therefore likely to contain proportionately large errors, as shown in Section 5. Even when damage is greater than $\$ 500$ million, estimates from different sources have been found to disagree by as much as $40 \%$.

Aggregation is one key to reducing estimation errors. To compare flood damages between states or river basins, it is advisable to aggregate the damage estimates over many years and compare the sums. To compare damage between years, it is advisable to aggregate yearly state damage estimates over multi-state regions, or river basin damages over large river drainage systems. Even when the estimates are highly aggregated, the user still needs to be aware that some of the variability is caused by error, and interpret the results accordingly.

## A. Analyzing Trends Over Time

There are several ways of looking at trends in flood damage. Economic damage results from an interaction between flood waters and human activities in the flooded area, so one must consider changes in population and development. Figure 7-1 shows (a) U.S. total flood damage, (b) flood damage per capita, and (c) flood damage per million dollars of tangible wealth. ${ }^{6}$ (All

[^8](a) U.S. Total Flood Damage, 1934-2000

Figure 7-1. Estimated annual flood damage in the United States, 1934-1999:
(a) Total flood damage.
(b) U.S. Per Capita Flood Damage, 1934-2000

Figure 7-1, continued. (b) Flood damage per capita.
(c) U.S. Flood Damage per Unit Wealth, 1934-1998

Figure 7-1, continued. (c) Flood damage per million dollars of tangible wealth.
estimates are adjusted for inflation.) The three graphs give quite different pictures of how U.S. flood damage has changed over time. Total damage and per capita damage show statistically significant increasing trends since 1934. On the other hand, damage per unit wealth has declined slightly, although the trend is not statistically significant $(a=0.05)$.

Caution \#1: In analyzing flood damage over time, it is important to control for changes in population, wealth, or development.

## B. Comparing States

Comparing states on the basis of their historical flood damage is complicated by the rarity of extreme damage. In a limited time period of study, some states will have experienced a lowprobability flood event and others will not. Damage totals for the period depend greatly on a few extreme events. Although aggregating state damage estimates over many years helps reduce estimation errors, it does not account for differences in the timing of severe damage. For example, the inclusion of data for just one more year, 1979, would change the position of Texas in the ranking of total damages in Figure 6-2, moving it from $6^{\text {th }}$ to $3^{\text {rd }}$ place (Section 6).

Figures 7-2 $(\mathrm{a}, \mathrm{b})$ compare rankings of the states based on their total flood damage in two periods, 1955-1978 and 1983-1999. Pennsylvania suffered the greatest damage in the earlier period, but its rank slips to $26^{\text {th }}$ in the later period. Iowa moves in the opposite direction, from $28^{\text {th }}$ in the earlier period to first in the later period. In both states, a single flood event determines the first-ranked status. A single year constitutes the majority of damage in many other states, as well. Differences in the timing and location of extreme weather events contribute to quite different rankings during the two periods.

Population differences are also an important factor when comparing states. In Figure 7-3, states are ranked according to their annual average damage per capita during 1983-1999, giving a quite different picture than the ranking by total damage in Figure 7-2(b). North Dakota moves to the top, with a whopping $\$ 363$ damage per person per year (mostly attributable to flooding in 1997), while California slips to $25^{\text {th }}$ place.

Caution \#2: When comparing damage in different geographical areas, it is important to control for differences in population and in the incidence of extreme weather events during the period of study.

## C. Comparing Individual Flood Events

In comparing annual state estimates, we recommend coarse comparisons using broad damage categories, perhaps similar to those used in Section 5 (low, medium, high, major). ${ }^{7}$ Uncertainty in the dollar estimates can make comparisons difficult, even in major floods where estimates are highly aggregated. Some of the difficulties are illustrated by the following comparison of two years of major flood damage (over $\$ 500$ million) in Minnesota in the 1990s.

[^9]
# Total Damage in Period (millions 1995\$) 

PERIOD= 1955 - 1978

Figure 7-2. States ranked based on total flood damage (a) during 1955-1978.

Total Damage in Period (millions 1995\$)
PERIOD $=1983-1999$

Figure 7-2, continued. (b) during 1983-1999.

Average Annual Damage per Capita, 1983-99 (1995\$)

Figure 7-3. States ranked based on average annual flood damage per capita, 1983-1999.

1993: Unusually heavy rainfall from May through August over most of the state produced widespread flooding that resulted in a presidential disaster declaration for 57 of Minnesota's 87 counties, and an agricultural disaster declaration for an additional eight counties. The NWS estimated damage of $\$ 1.0$ billion (in 1995 dollars).

1997: Heavy snow and ice followed by spring rains and rapid snowmelt led to severe flooding in April and May. Damage was extensive in East Grand Forks and many smaller communities. A presidential disaster declaration was issued covering 58 Minnesota counties. Additional storms and flooding in June and July led to another disaster declaration for 7 metropolitan area counties. The NWS estimated damage of $\$ 715$ million (in 1995 dollars).

In which year was the damage more severe? The answer to this question depends upon how "severe" is defined. The NWS estimates suggest that damage was substantially greater in 1993. However, a report issued by the Minnesota Department of Public Safety leads to the opposite conclusion. Table 7-1 shows actual costs reported in A Decade of Minnesota Disasters (MDPS 2000). (We have excluded costs that are not associated with direct damage, such as temporary housing, hazard mitigation, and economic injury due to loss of business.) FEMA assistance programs, insurance, and SBA loans all indicate that non-agricultural losses were much higher in 1997 than in 1993. A representative of Minnesota's Division of Emergency Management reinforced this conclusion, telling us that in 1997 entire Minnesota towns were flooded, while in 1993 the main effects of the great Midwest flood occurred in states farther south (Sherrill Neudahl, personal communication, 10/5/00).

Agricultural damage was greater in 1993 than in 1997, however. The value of Minnesota's final crop output in 1993 was $44 \%$ less than the average of the previous three years (USDA 2000). In contrast, final crop output in 1997 was equal to the average for the previous three years, suggesting that the floods did little to diminish agricultural productivity that year. Twice as much money was awarded in FSA loans to Minnesota farmers in 1993 as in 1997 (Table 7-1).

Lumping agricultural and non-agricultural losses into a single damage estimate is problematic. Enormous discrepancies are found in historical estimates of agricultural damage because of different perspectives on and methodologies for the measurement of losses. For example, one official publication estimated that Minnesota's total damage in the 1993 flood exceeded $\$ 1.7$ billion (MDPS 1994) - substantially more than the NWS estimate. Of that, $\$ 1.5$ billion was attributed to crop "losses" based on the amount that crop production fell short of the previous 4-year average. This is a loss in expectation, perhaps, but not a loss of actual investment.

This comparison does not lead us to challenge the NWS estimates for these two flood years. Rather, it provides another reason for caution in interpreting and comparing damage estimates. Given the error magnitudes found in Section 5, the difference of $40 \%$ in estimates for the two years is not large enough to say with confidence that one year's economic damage was worse than the other's, only that there was major damage in both years. Most Minnesotans would

[^10]probably consider the floods of 1997 to be much more severe than those of 1993, while farmers might hold the opposite view.

Caution \#3: Because of the large estimation errors found in the NWS data, estimates for individual floods should be used with caution. For some purposes the comparison of individual floods may be better done using nominal or ordinal data categorizations. For specific events, detailed descriptions should be sought to compare the nature and impacts of the damage.

## D. Possible Inconsistencies With Other Sources

The NWS defines flood damage more narrowly than many other agencies. Emergency management agencies generally include both river and coastal flooding whenever water rises to overflow land that is not normally submerged. In contrast, the NWS estimates include only flooding whose primary cause is rainfall, snowmelt, or river flows, excluding flooding caused by wind-driven waves associated with coastal storms or hurricanes. For example, FEMA records show a Presidential disaster declaration of type "flood" for Massachusetts in February 1978, and the USACE reports $\$ 520$ million flood damage due to storm surge and huge waves (USACE New England Division 1979; converted to 1995 dollars), but that damage is not included in NWS flood damage estimates.

The NWS estimates do include floods caused by dam failure, however. In the NWS record, Idaho's worst flood resulted from the failure in 1976 of the newly-constructed Teton Dam, with damage estimates in the $\$ 1-2.3$ billion range (in 1995 dollars). Idaho's largest estimated flood damage due to natural causes was much smaller: \$120 million in 1997.

Caution \#4: Different agencies define "flood" and "flood damage" somewhat differently. Check for incompatibilities between data from different sources before seeking to combine sources or aggregate data.

## E. Uses of the Reanalyzed NWS Damage Estimates

With the precautions noted above, we conclude that the reanalyzed NWS flood damage estimates can be a valuable tool to aid researchers and decision makers in understanding the changing character of damaging floods in the United States. Data sets of annual damage at national, state, and river basin levels are available at www.flooddamagedata.org.

In climate research, these data can contribute to understanding the relationship between climatic influences and damaging floods. For example, they have been used to examine the relationship of national and regional flood damage with several measures of precipitation, in a study that controlled for changes in population and wealth (Pielke and Downton 2000). For policy makers and emergency managers, the data provide a nationwide overview of flood vulnerability and can be useful in evaluating policies related to management of flood hazards. For example, we have investigated the role of politics in presidential disaster declaration decisions by comparing disaster declarations involving floods with estimated flood damage (Downton and Pielke 2001).

## F. Recommendations for Future Collection of Flood Damage Estimates

A series of natural disasters in the 1990s, accompanied by skyrocketing costs of federal disaster assistance, has prompted calls for development of national databases to record losses from past and current disasters (Mileti 1999, NRC 1999, Heinz Center 2000). The NWS damage estimates are not reliable enough to be a basis for certain decisions regarding flood policy, such as setting specific flood insurance premiums or evaluating the cost-effectiveness of particular hazard mitigation measures. Better damage data are needed to evaluate the effectiveness of mitigation measures designed to reduce flood losses.

Substantial improvement of flood damage records in the U.S. would require additional funding and should have a clear purpose based on intended uses of the data. A committee of the National Research Council (NRC) points out that reliable loss data are critical for cost-effective hazard mitigation and planning for future disaster response. The NRC (1999) report recommends measures for developing a comprehensive and consistent database of losses resulting from natural disasters. Recommendations include:
(1) One agency of the federal government should be responsible for compiling the loss data, working with states and localities to collect the data. The Bureau of Economic Analysis (BEA) within the Department of Commerce is suggested as the agency best-suited to the task.
(2) The data should focus on direct losses (loss in asset value), including losses that are not reimbursed by insurance or disaster aid.
(3) A uniform framework should be used in reporting and compiling loss estimates, classified according to who initially bears the loss (government, businesses, individuals, etc.) and the type of loss (property, agricultural products, deaths and injuries, cleanup and response costs, temporary housing, etc.). These loss estimates should be more complete and accurate than the initial estimates made at the time of a disaster and should include events that may not qualify for a presidential disaster declaration.
(4) The database need not contain loss information for every event; rather, the objective should be to compile data on disasters that cross some threshold. The definition of a "major" natural disaster for which loss data are to be compiled should be consistent with expectations for how the data will be used.

Clearly, the NWS flood damage database does not provide the level of accuracy and detail envisioned in the NRC recommendations, nor is it intended to do so. Nevertheless, the collection of damage information in severe weather events by NWS field offices provides a model, of sorts, for nationwide collection of damage data. It is administered fairly uniformly throughout the nation, collects information on multiple natural hazards, focuses on direct losses including some unreimbursed losses, and is not limited to declared disasters. As the NWS field offices collect storm damage information, they are in a good position to identify weather events that appear to meet whatever minimum criteria might be established for loss data to be compiled.

In the absence of additional funding, only minor improvements can be expected in the NWS collection of flood damage estimates. The following modest changes are suggested to improve accuracy, consistency, and usefulness.
(1) Clearly define the purposes of the damage estimates and what types of loss are to be included.
(2) Provide uniform instructions to staff members responsible for compiling damage estimates at all NWS field offices. Instructions should include how to obtain damage estimates and some training in damage estimation.
(3) It would be valuable to provide separate estimates of different types of loss, as was done in Climatic Data National Summary through 1975. At a minimum, distinguish on-farm losses of agricultural products from other property losses.
(4) It is reasonable to set a lower limit below which loss estimates need not be reported, such as $\$ 50,000$ for a single flood at the county level. The NWS-HIC practice of focusing greatest attention on floods with damage greater than $\$ 1$ million at the state level is also reasonable. These practices would save staff time and have little impact on total damage estimates.

## Appendix A

## COMPILATION OF DAMAGE ESTIMATES FOR 1976-1979

Monthly damage estimates by river basin in 1976 and 1977 were published in Climatological Data National Summary. NWS staff prepared some 1978 and 1979 estimates which were summarized in Weatherwise (Marrero 1979, 1980). We augmented these estimates with unpublished information housed at NWS-HIC, including reports from regional NWS offices, preliminary tabulation sheets, and notes made by NWS employees. Wherever possible, we also compared damage estimates from NWS-HIC files with reports on specific floods by other agencies, including USACE, USGS, and NOAA. Final estimates were chosen using the following rules:

- In order to change any estimates in the NWS tabulated data set, a published source had to provide good reason to doubt the NWS estimates and the published source had to provide more reliable estimates.
- There were instances when we had to choose between two or more estimates. In general, we chose published source estimates over NWS "grey" sources.
- Asterisks were added to the estimates wherever published sources indicated that a damaging flood occurred but provided no estimates.

## 1976 Flood Damage Estimates

Reconstructed 1976 damage estimates by state and month are shown in Table A-1. Data sources are as follows:

- September in California is from the NOAA Cooperative Observer (NOAA 1976).
- July in Colorado is from a USGS/NOAA report (1979).
- May in Oklahoma is from a report concerning flood hazard mitigation in Oklahoma (Patton 1993).
- All other damage estimates are from NWS notes and summaries archived at NWS-HIC, which had been compiled for publication in Climatological Data National Summary, but had not been published.

## 1977 Flood Damage Estimates

Reconstructed 1977 damage estimates by state and month are shown in Table A-2. Data sources are as follows:

- The following totals are from USACE reports: October in Arizona (USACE, Los Angeles District 1978) and December in Oregon and Washington (USACE, Portland District 1978).
- The estimate for a flood in Kansas City, Kansas and Kansas City, Missouri in September of 1977 is from NOAA (1977) and USGS (1991) reports.
- 1977 damage totals for Tennessee, Virginia, and West Virginia have been changed based on information on April flooding in Appalachia from a TVA flood report (TVA 1978).
- All other damage estimates are from NWS notes and summaries archived at NWS-HIC.

## 1978 Flood Damage Estimates

Reconstructed 1978 damage estimates by state and month are shown in Table A-3. It was more difficult to piece together the flood estimates for 1978 and 1979 than for 1976 and 1977.

Several different sets of state-level estimates exist in the NWS files for 1978, and in many cases the estimates do not agree. Data sources are as follows:

- All estimates for California are from the California Office of Emergency Services (Montane 1999).
- Most of the entries represented by asterisks rather than damage figures are based on information in Storm Data. In these cases it was apparent that flooding had occurred, but damage figures were not available.
- The following numbers are from USACE reports: March in Arizona (USACE, Los Angeles District 1979a); March in Ohio (USACE, Buffalo District 1978); August in New Mexico (USACE, Albuquerque District 1978); September in Arkansas (USACE, Little Rock District 1978); September in Texas (USACE, Albuquerque District 1979a); December in Arizona (USACE, Los Angeles District 1979b and USACE, Los Angeles District 1980); and December in New Mexico (USACE, Los Angeles District 1980).
- Montana and Wyoming in May are from a jointly authored USGS/NOAA paper (USGS 1984).
- The following estimates are from Marrero (1979): March in Nebraska and Indiana; April in North Dakota and Virginia; May in Louisiana and Texas; July in Alabama, Minnesota, and Wisconsin; August in Texas; and September in Louisiana.
- The following estimates are from Storm Data: May in Arkansas; July in Colorado; August in Illinois, Indiana, and Maryland; and December in Idaho.
- All other estimates are from NWS files.

## 1979 Flood Damage Estimates

Reconstructed 1979 damage estimates by state and month are shown in Table A-4. Data sources are listed below. Users of 1979 estimates should note that a flood in "New Jersey, New York, and southern New England" in January caused $\$ 62$ million in damage (Marrero 1980). This estimate could not be assigned to individual states. Similarly, a flood in April in Louisiana, Mississippi, and Alabama caused $\$ 1$ billion in damage that could not be assigned to individual states (Marrero 1980). These floods are included in the national total for 1979, but not in the state estimates.

- All estimates for Virginia are from the state emergency management office (Michael Cline, personal communication 2000).
- The following estimates are from Marrero (1980): March in Indiana and Iowa; April in Texas; July in Texas; September in Maryland, Louisiana, and Texas; October in Kansas and Florida; and November in Hawaii.
- The following are from USACE reports: March in Minnesota and North Dakota (USACE, St. Paul District 1979) and June in New Mexico (USACE, Albuquerque District 1979b).
- Estimates from Storm Data include: February in Arkansas; April in Arkansas, Florida, Illinois; March in Florida and New York; May in South Dakota; June in Colorado; July in Alabama, Illinois, New York, and West Virginia; August in Minnesota, Utah, and West Virginia; and September in Florida.
- February in Hawaii is from USGS (1991).
- April in Ohio is from NWS notes.
- All other estimates are from NWS files.

## Appendix B

## ESTIMATED FLOOD DAMAGE, BY STATE

Damage estimates are given in current dollars for the year in which the damage occurred. To adjust for inflation, the estimates can be converted to 1995 dollars by dividing by the implicit price deflator in Column 2 (U.S. Bureau of Economic Analysis 2001). Estimates are for calendar years during 1955-1979, and for fiscal (or water) years during 1983-2000. For example, fiscal/water year 1990 covers from October 1, 1989, through September 30, 1990.

An entry of zero indicates that no damage estimate was reported. It can be assumed that actual flood damage was small, but it is quite possible that some damage occurred.

Data are unavailable for 1980-1982 and for Alaska before 1967.

[^0]:    *The National Center for Atmospheric Research is sponsored by the National Science Foundation.

[^1]:    * Source: U.S. Bureau of Economic Analysis, 2001.
    - Data unavailable, see text for discussion.

[^2]:    ${ }^{1}$ Michael Sabbaghian, Deputy Public Assistance Officer for the California OES, manages disaster recovery activities for infrastructure and is responsible for grant management. He explained the process for estimating and recording losses in presidentially declared disasters. He also provided the damage estimates and cost data for the 1998 California El Niño disaster, which is used in this section.

[^3]:    * Proportion of actual cost (\$279 million) of cases with an IDE.

[^4]:    ${ }^{2}$ States that responded were AL, CA, CO, FL, GA, HI, IL, IN, LA, MA, MI, MN, MO, OH, OR, SC, TX, VA, WA, WV, WY.

[^5]:    ${ }^{3}$ Estimates for 1980-82 were included at this stage of the analysis. California flood damage in Dec 1982 could be attributed differently by the two sources because of the overlap in definition of calendar year 1982 and fiscal year 1983. The other four states did not report losses in Oct-Dec 1982.
    ${ }^{4}$ During 1955-98, California reported losses in 26 years (59\%), while Colorado reported losses in only 13 years ( $30 \%$ ). The other three states reported losses in $33-41 \%$ of the years covered by their reports (8 years in Michigan, 9 years in Virginia, and 8 years in Wisconsin).

[^6]:    * Estimates of maximum damage can be misleading. For example, in Idaho the maximum was caused by failure of the Teton Dam in 1976; the worst damage directly from precipitation and streamflow is estimated at $\$ 120$ million. In Texas, the maximum appears small but much greater damage occurred in a year not covered by this table (\$3.76 billion in 1979).

[^7]:    ${ }^{5}$ The largest known omission - of $\$ 50$ million damage in California in 1979 - occurred when NWS data collection had been seriously curtailed. It has been corrected in the revised data sets that we provide.

[^8]:    ${ }^{6}$ Flood damage per capita is computed by dividing the inflation-adjusted losses for each year by the estimated population on July 1 of that year (www.census.gov). Flood damage per million dollars of tangible wealth uses the net stock of fixed reproducible tangible wealth as estimated by the U.S. Dept. Of Commerce, Bureau of Economic Analysis (www.bea.doc.gov) for December 31 of each year (depreciating stock carried over from prior years). Thus, the flood damage per million dollars of tangible wealth reflects the proportion of the nation's wealth in that year lost due to floods. All three damage time series have log normal frequency distributions, therefore the displayed trends are transformations of linear trends computed on the logarithm of the damage values.

[^9]:    ${ }^{7}$ For comparing floods at the county level, where damage estimates are extremely unreliable, damage categories can be based on descriptive information instead of dollar estimates. This approach was used in a study of flooding in two Iowa counties (Pielke et al. 2000).

[^10]:    * FEMA-993-DR-MN in 1993; FEMA-1175-DR-MN and FEMA-1158-DR-MN in 1997.

[^11]:    * indicates that a flood occurred, but damage figures are unavailable or under $\$ 30,000$.
